January 11th, passed a good night; general condition same. The patient is apathetic, complains of great weakness, and is quite cyanotic. At 8 A.M., temperature, 100.6° F.; respiration, 24; pulse, 90. At 8 P.M., temperature, 100.8° F.; respiration, 20; pulse, 100. The pulse irregular and intermittent. Bowels still constipated, and respond only slightly to high enemata. Urine, fifty-two ounces; specific gravity, 1.008; contains albumin, granular and epithelial casts, blood, and pus cells.

January 12th, has pain in the right shoulder, and coughs. General condition bad; pulse very poor, rapid, irregular, dicrotic, and intermittent, running as high as 124. At 8 A.M., temperature, 102.2° F.; respiration, 24; pulse, 114. At 8 P.M., temperature, 101.6° F.; respiration, 30; pulse, 120. Urine, thirty-six ounces. Ammonium carbonate, five grains every three hours.

January 13th, very drowsy; pulse imperceptible, respirations very rapid. At 8 A.M., temperature, 100.2° F. At midday pulmonary œdema, and death at 2 P.M. (See Chart III.)

The results of the autopsy, which was performed by Dr. F. S. Mandelbaum two hours after death, were as follows:

Body emaciated; rigor mortis absent.

Lungs: Right—voluminous; no adhesions; lower lobe firm and completely consolidated; crepitation absent; red hepatization. Left—old adhesions at the apex and a few recent ones at the base; the entire lung atrophic; at the apex there was an old healed tuberculosis, with many fine sand-like concretions.

Heart: Small and atrophic. Mitral valves thickened; aortic cusps much thickened and somewhat adherent to the aorta by old endarteritis. Atheroma of the aorta. Coronary arteries patent. Muscle friable.

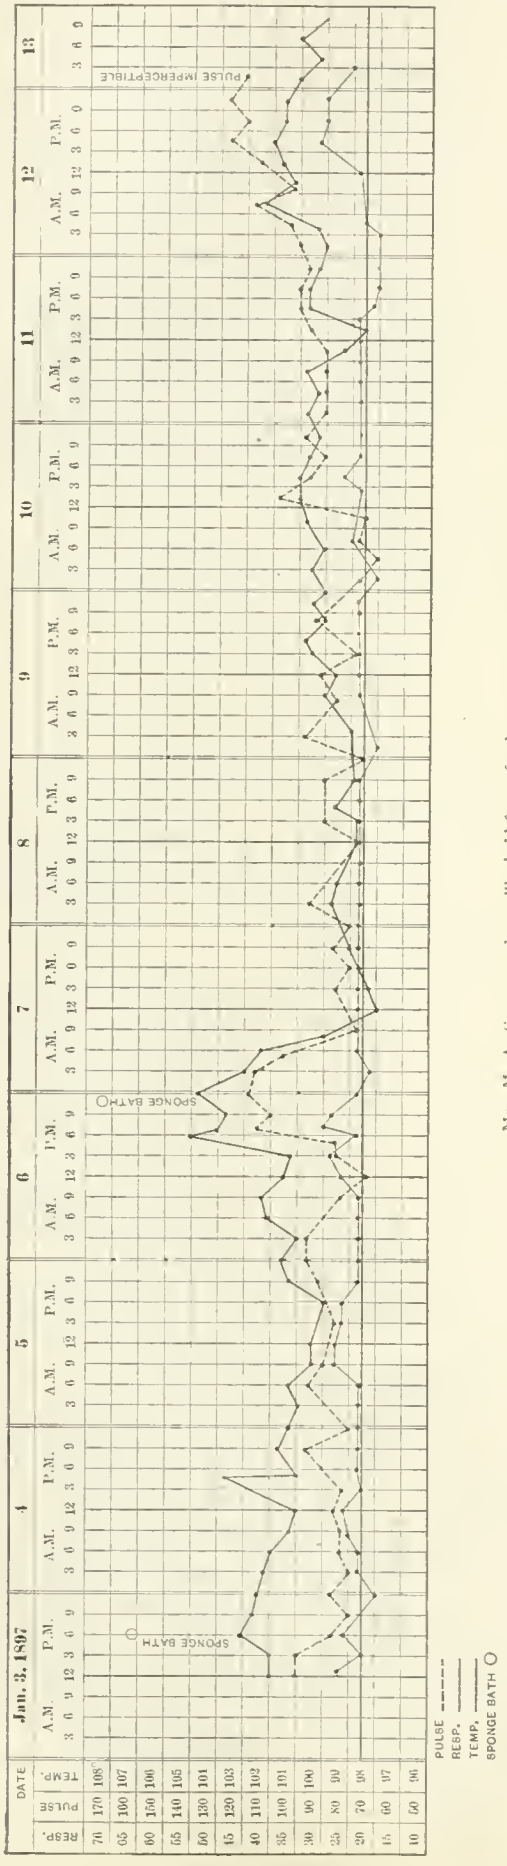
Spleen: Slightly enlarged, dark in color; consistence quite soft. Cultures which were made developed pure growths of typhoid bacilli. The microscope also showed the characteristic clumps of Loeffler.

Liver: Negative. The same was true of the stomach and pancreas.

Intestines: The small intestines were somewhat congested. Enlarged Peyer's patches were found for eighteen inches above the ileo-cæcal valve; the

patches were necrotic, and there was a thinning of the wall of the gut, which was dark and congested. In the cæcum and the colon the mucous membrane was

CHART III.



Mrs. M. A. S——, aged 72. Typhoid fever, fatal.

œdematous and congested. The solitary follicles were enlarged and prominent.

Blood: Cultures taken from the blood of the inferior vena cava grew pure colonies of typhoid bacilli (Dr. Elsberg).

Case II.—J. B——, Russian, sixty-three years old, admitted to my service at Mount Sinai Hospital, January 5, 1897.

Family history, negative.

Previous history, negative.

Present history: For some time (exact date cannot be elicited) has been complaining of severe headache, chills, fever, and sweating. The latter usually occurs in the morning. Insomnia; anorexia; no vomiting. Constipation. Has slight cough; palpitation. Has pain on urination. Complains especially of headache and chills.

On admission, general condition poor; panniculus fair.

Lungs: Anteriorly—dull note in right axillary line; crepitant and subcrepitant râles. Posteriorly—high-pitched note over right apex; dull note over rest of chest. Few subcrepitant râles over both bases; increased voice and breathing over right side.

Heart: Sounds feeble, but no murmurs.

Liver: Enlarged and palpable two finger-breadths below free border of ribs.

Spleen: Negative.

Otherwise abdomen negative. No eruption visible. No œdema. Reflexes normal. Weight, one hundred and twelve pounds.

Urine, acid; urate deposit; specific gravity, 1.015; no albumin or sugar; a few epithelial and pus cells.

On admission, at 2 P.M., temperature, 98.6° F.; respiration, 20; pulse, 80. Ordered calomel, rhubarb, and soda.

January 6th, at 8 A.M., temperature, 99.8° F.; respiration, 20; pulse, 64. At 8 P.M., temperature, 100.2° F.; respiration, 24; pulse, 62. Highest temperature at 4 P.M., when it was 101.2° F.

January 7th, slept fairly well. Enema caused large formed yellow stool. At 8 A.M., temperature, 100° F.; respiration, 24; pulse, 60. At 8 P.M., temperature, 102° F.; respiration, 20; pulse, 72.

January 8th, very restless all night. Temperature rose from 102.8° F. at 2 A.M. to 104° F. at 6 P.M.; dropped to 103.8° F. at 8 P.M. after five grains of phenacetin. At 10 P.M. it rose to 105° F.; at 12 midnight it dropped to 103° F. Respirations varied between 24 and 28: pulse between 64 and 86. Cold compresses over chest. Two stools.

January 9th, temperature at 2 A.M. was 103° F.; then it gradually fell to 100° F. at 8 A.M.; it rose to 102.4° F. at 6 P.M. Respiration between 24 and 32; pulse, 62 to 76.

January 10th, at 2 A.M., temperature was 99.8° F., greatest rise being to 102.6° F. at 8 P.M. Respirations between 24 and 30; pulse between 56 and 76. Examination of blood failed to reveal any plasmodia malariæ or any polynuclear leucocytosis.

January 11th, at 2 A.M., temperature, 102.4° F.; slept very little. Few crepitant râles at left base; bronchial breathing at right base. Complains of weakness. Temperature ranged between 100 and 102.4° F.; respiration averaged 24; pulse between 56 and 64.

January 12th, sleepless night. Area of dulness and bronchial breathing over left scapular region, with crepitant and subcrepitant râles. Fever was 100° F. at 2 A.M.; 104.4° F. at 8 A.M., and gradually fell to 98.6° F. at 6 P.M. Had a chill at 6 A.M. preceding this rise. No antipyretics except cold compresses. Respiration ranged between 20 and 26; pulse, 56 to 98.

January 13th, had fairly good night. Temperature

low till 4 P.M., when it rose to 102.4 F., reaching maximum of 103.4 F. at 8 P.M.; respiration, 24 to 28; pulse, 60 to 88. Enema produced large soft yellow stool.

January 14th, temperature subnormal till 6 A.M., when it was 97.6 F.; then rose at 2 P.M. to 102.4 F., falling to normal at 8 P.M. Respiration, 24 to 28; pulse, 60 to 70. Physical examination showed dull note with increased breathing over left base; also crepitant and subcrepitant râles. Involuntary stool at 5 P.M.

January 15th, temperature rose at 8 A.M., reaching maximum of 103.6 F. at 10 A.M., accompanied by chill lasting fifteen minutes; then gradually reached normal at 4 P.M. Respiration, 24; pulse, 76 to 88.

January 16th, temperature, 99 F. at 6 A.M.; 100.2 F. at noon; 102° F. at 2 P.M.; 105.2 at 5 P.M.; then declined to normal after fifteen grains of quinine. Respiration, 24 to 30; pulse, 84 to 100.

January 17th, subnormal temperature (97.8° F.) at 6 A.M.; began to rise at noon, reaching 101 F. at 6 P.M. Quinine, ten grains, t.i.d. Respiration, 24 to 28; pulse, 80 to 96. Five small loose yellow stools.

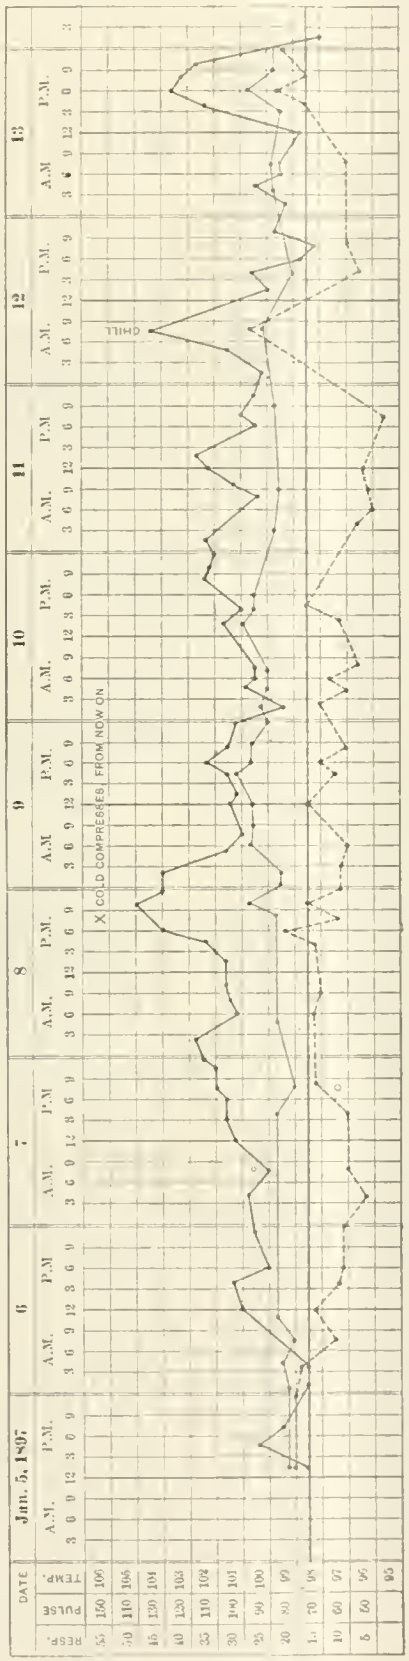
January 18th, temperature rose at 10 A.M. to 102.6 F.; maximum, 103.6 F., at noon. Phenacetin, five grains, reduced it to 100 F. at 4 P.M. Quinine, ten grains, t.i.d. General condition poor; apathetic; refuses medicines. Respiration, 24; pulse, 68 to 80.

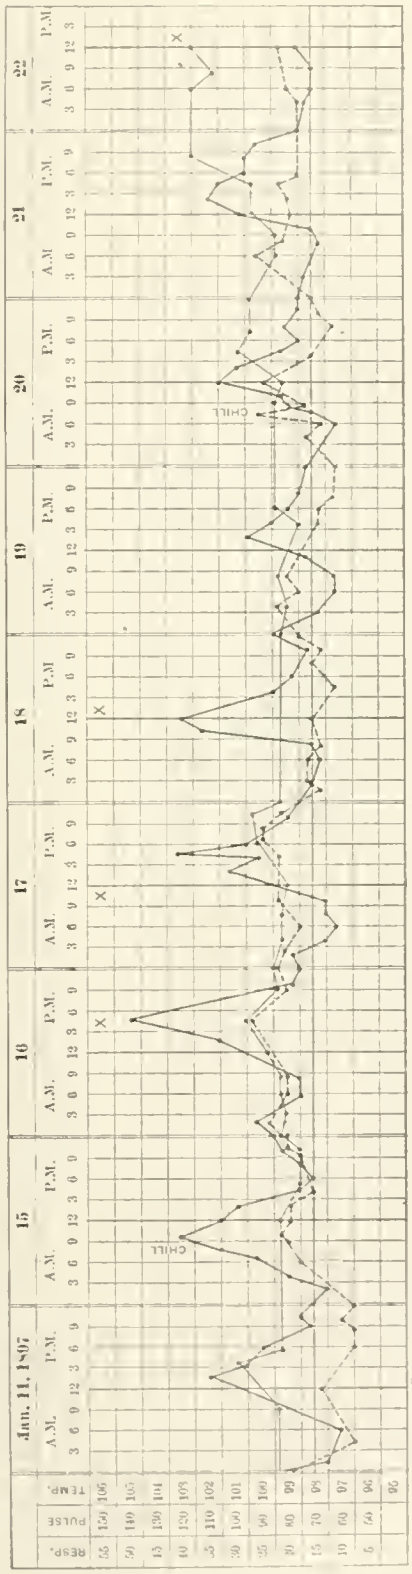
January 19th, temperature subnormal till 2 P.M., when it rose to 101° F., falling to 100 F. at 4 P.M. Respiration, 24; pulse, 68 to 86. Widal test reported as doubtful.

January 20th, restless. Chill at 8 A.M. Physical signs at left base still present. Liver extends to four finger-breadths below free border of ribs; tenderness in right hypochondrium. Temperature normal till noon, when it rose to 102° F., in spite of the quinine, falling steadily thereafter. Respiration, 24 to 32, pulse, 76 to 92.

January 21st, restless; general condition bad; cyanotic, looks septic. Temperature normal till noon, when it rose to 101.2 F., declining after 6 P.M., and reaching 99° F. at midnight. Vomited dark fluid at 6 P.M.; at the same time respiration rose to 40, pulse remaining at 80; temperature, 101° F.

CHART IV.



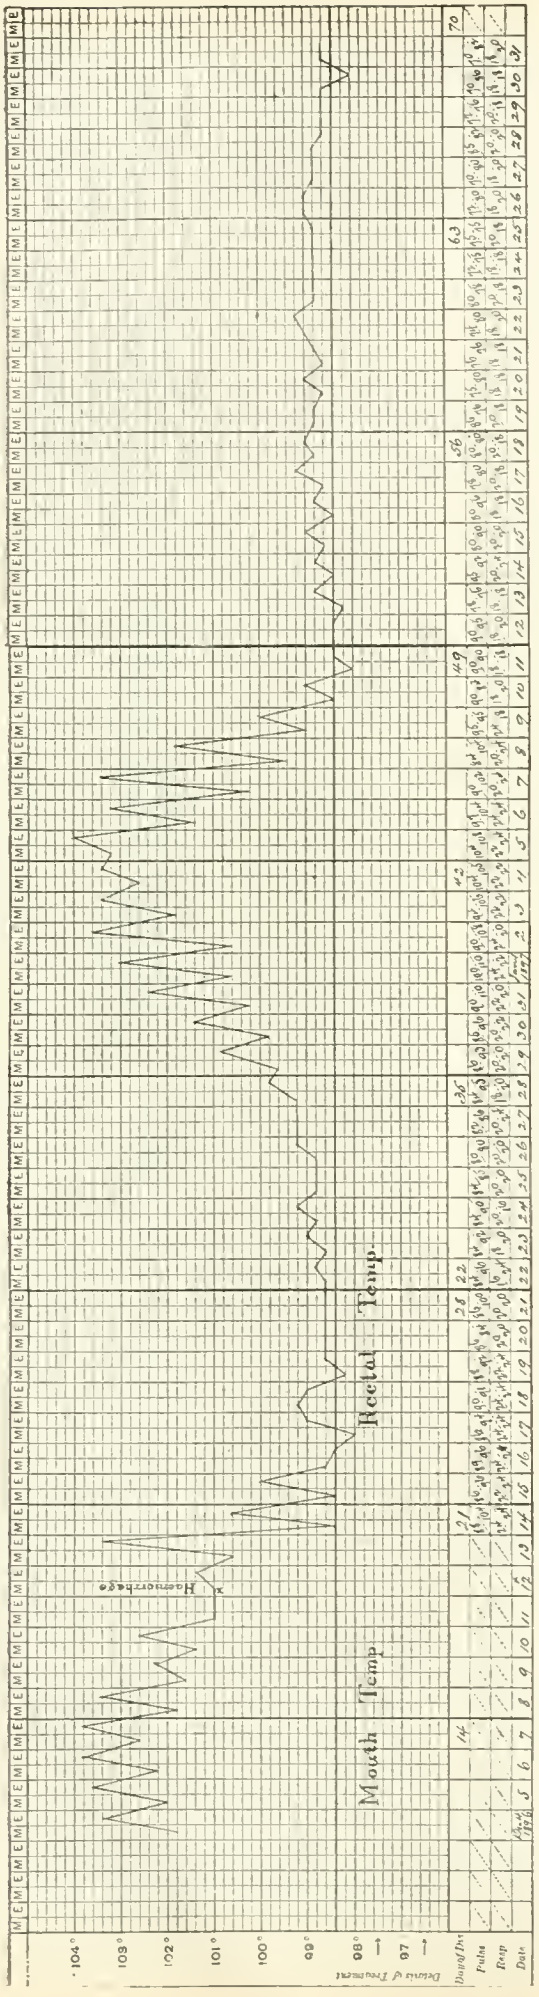


J. B——, aged 63. Typhoid fever, fatal.

January 22d, liver aspirated with negative results. Temperature normal; respiration, 40; pulse, 80 to 86. Stupor; died suddenly at 1 P.M.

No autopsy allowed; spleen aspirated, pure cultures of typhoid bacilli obtained from the blood. (See Chart IV.)

CHART V.



Case III. (Dr. Kohn).—Mr. G——, aged sixty-two.

Previous history: Had typhoid fever when seventeen years old. This attack was said to have been very severe, and lasted six or seven weeks. He had suffered from symptoms of rheumatism for the past fifteen years. He had also had difficulty in urinating for thirty years or more. Myocardial symptoms had been present for six years.

Present attack: When first seen, on the afternoon of December 4, 1896, he said that he had felt very ill for the past week; complained especially of being very weak and feverish; had constant vertigo. Constipation. Temperature, 101.8° F.; pulse, slow, irregular, and weak.

The temperature curve followed the typical course, showing evening rises, which gradually increased, with morning remissions. No typical eruption at any time. Spleen but slightly enlarged. The only symptoms were the general weakness, attacks of vertigo, marked constipation, and frequent attacks of distressing tympanites. He passed large quantities of gas.

On December 12th he had a severe intestinal hemorrhage. Very slight bronchitis. In the third week he developed cystitis, which was afterward found to be due to vesical calculi.

On December 19th the temperature was normal and remained so till the 28th, when he had a typical relapse of three weeks, lasting till January 11th. This curve was also characteristic. (See Chart V.)

Throughout the disease the heart action was slow, weak, and irregular. The only nervous symptom was extreme restlessness.

The convalescence was rapid, so that about a month later litholopaxy was performed under cocaine; this failing to relieve the bladder trouble, suprapubic cystotomy was performed under chloroform one month later. The man has been in good health ever since.

Case IV. (Dr. Rudisch).—Mr. X——, sixty-six years old.

May, 1897, when first seen, he said that for the past few days he had had great general weakness. No cause could at first be found for this, but as time went on he gradually developed the characteristic symptoms of typhoid fever. The attack was in every way typical. The highest temperature was 105° F. At that time he was delirious for three days. Once he had some blood in the stools. He also had a marked bronchitis, so that a pneumonia was at one time suspected. Roseola scanty and vaguely marked. Spleen decidedly enlarged. No diarrhœa. The Widal reaction was present after the seventh day, and persisted for three months. The convalescence was very slow, six months elapsing before his strength fully returned to him. He is now perfectly well.

Case V.—Mr. J. H. C——, aged sixty-five; hotel keeper. Admitted to Mount Sinai Hospital (service of Dr. Rudisch), on October 27, 1897.

Family history, negative.

Previous history, only minor complaints.

Present history is of three and one-half weeks' standing. It began with a loss of interest in everything, inability to be about, and general malaise. He also had great difficulty in breathing. Feeling sure that he had typhoid fever, and knowing that illness would injure his business, he came to this city and had been in bed under medical attendance for one week before entering the hospital. He now complained of headache, slight cough, and great dryness of the mouth. He had had no epistaxis; the bowels had been constipated since the onset. No cardiac or urinary symptoms. Sense of hearing and of smell impaired. Marked anorexia. He said that at the beginning he had severe chill and fever.

Physical condition on admission: General state is

fair; is well nourished; the tongue is glazed, cracked, and coated.

Lungs: Anteriorly and posteriorly the percussion note is rather tympanitic; prolonged expiration.

Heart: The cardiac area is somewhat enlarged. Slight blowing systolic murmur at the apex. Apex beat is imperceptible. Second aortic sound accentuated. The pulse is slow, regular, and slightly dicrotic.

Abdomen is somewhat tympanitic. No eruption.

Liver: Extends from the fifth space to three finger-breadths below the costal border. The region of the gall bladder is very tender to the touch.

Spleen: Enlarged to percussion and palpable.

No œdema of legs.

At 11 A.M., on admission, temperature, 101.2° F.; pulse, 84; respiration, 24. At 11 P.M., temperature, 102.6° F. Urine: specific gravity, 1.022; acid, trace of albumin, trace of indican, positive Ehrlich reaction; few red and white blood cells and urates.

October 28th, temperature ranged between 101° and 102.4° F.; pulse, 84 to 100; respiration, 24. Enema required.

October 29th, temperature, 100° to 101.6° F.: pulse, 72 to 96; respiration, 24. Enema necessary.

October 30th, temperature, 99.8° to 100.6° F. General condition good, but tongue still glazed.

October 31st, temperature, 99.4° to 100.8° F. Widal reaction absent.

November 1st, unchanged; general condition good. Temperature, pulse, and respiration about the same.

November 2d, Widal reaction positive (board of health report).

November 5th, temperature keeps ranging between 99° and 101° F.; pulse about 80; respiration, 24. The tongue becoming moist and clean. Mental condition good.

November 7th, at 11 P.M., temperature rose to 102° F., pulse to 90.

November 8th, temperature gradually fell to 99.8° F. at 2 P.M., and then rose to 101.2° F., remaining at this level till 5 A.M. It gradually fell to 99.2° F. at 5 P.M. (November 9th). Soon after it rose to 101.2° F., and kept between 102° and 99.8° F. General condition excellent.

November 15th, temperature normal, and patient convalescent.

Diagnosis.—In the typical cases which follow the ordinary course, no difficulty is encountered; but in the atypical ones it is often impossible to make it during life. The reason for this may be referred to the great variations in the clinical picture, as shown above. Then, too, cases are undoubtedly not infrequently overlooked because the disease is currently supposed to be such a great rarity in the aged. Our improved methods of bacteriological diagnosis ought to be of great value, especially in these cases.

The conditions which must be differentiated in the diagnosis are senile asthenia, senile pneumonia, gastro-intestinal inflammations and auto-intoxication, nephritis, and cerebral disorders like meningitis and thrombosis.

Prognosis.—This is grave, especially in the atypical cases. However, recovery is by no means rare. The protracted convalescence renders the patients peculiarly liable to death from intercurrent complications. According to Murchinson,[1] the mortality above fifty years is 34.94 per cent. Uhle states that 52.6 per cent. of the cases above forty years are fatal. Of the five cases I have reported, the two atypical ones terminated fatally, the three typical cases ended in recovery (60 per cent.).

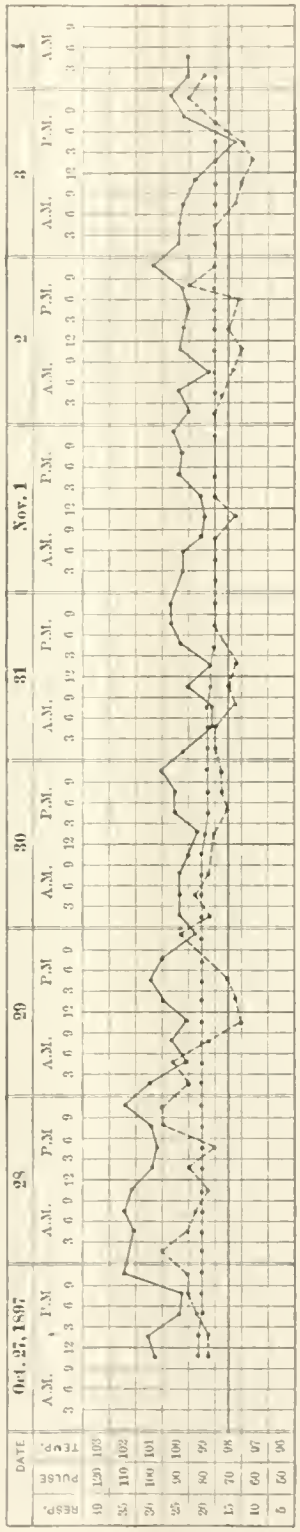


CHART VI.

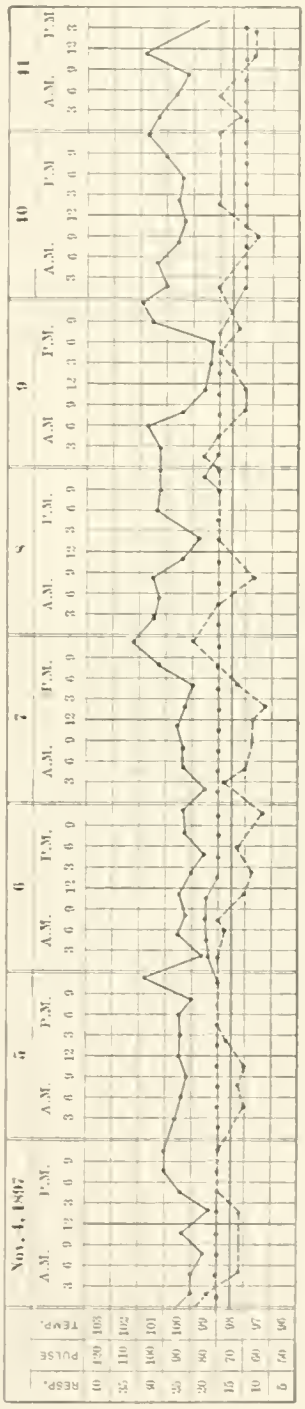

J. H. C——, aged 65. Typhoid fever, recovery.

Treatment.—The special features of the treatment of the disease in the aged are well stated by Boy-Tessier: "To combat the adynamia with tonic treatment; to guard against pulmonary complications; to watch the heart, especially its right side. Baths are to be avoided on account of the atheromatous condi-

tion of the blood-vessels. Good results may be obtained from systematic cold enemata. Tepid baths are also serviceable. Cardiac tonics, like theobromine, caffeine, and alcohol, are very useful." Otherwise, the indications for treatment are the ordinary ones for the disease as it occurs in younger persons.

ANÆSTHESIA—"GAS AND ETHER."

By THOMAS L. BENNETT, M.D.,

ANÆSTHETIST AND INSTRUCTOR IN ANÆSTHETICS, HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

The disagreeable phenomena accompanying the induction of ether anæsthesia by ordinary methods constitute a picture familiar to all who administer this agent. They depend, at the beginning, upon the pungency of the vapor, causing holding of the breath, swallowing-movements, coughing, choking, and suffocative sensations from closure of the glottis, and various emotional disturbances in certain patients. At a later period they are due to its stimulating effect, resulting in excessive activity of the muscular, respiratory, and circulatory systems, disordered cerebration, increased lacrymation and salivation; thus constituting the "stage of excitement." These distressing effects of ether are responsible for most of the opposition which many have to its use and for much of the annoyance and danger attending its administration.

Various means have been employed to obviate or lessen these effects; notably, beginning the administration with chloroform or with mixtures containing chloroform, giving certain drugs, as chloral, alcohol, or morphine before the etherization, the preliminary application of local anæsthetics to the upper air passages, and others. These measures are more or less successful, but are open to certain objections. Beginning the administration with chloroform exposes the patient to much of the danger of that drug, since about one-half of the chloroform deaths have occurred before the anæsthesia has become complete. Mixtures of chloroform and other anæsthetics are much less dangerous and are quite satisfactory. The A.C.E. mixture or the Schleich solutions will be found to serve this purpose well. The administration of chloral or alcohol in sedative doses previous to the etherization is objectionable, for the reason that in such doses both are depressants. Opium before ether undoubtedly renders the anæsthesia quieter at all stages, but the opium effect continuing, as it does, so long after the etherization, is often a disadvantage. The doses of opium commonly exhibited before anæsthesia are larger than are necessary to produce favorable effects; this is due to the fact that its action is greatly intensified in the presence of other narcotics. Instead of one-eighth to one-third grain doses of morphine before ether, doses varying from one-twentieth to one-eighth grain, according to the type and condition of the patient, are satisfactory; furthermore, the larger doses of opium, when given as a routine practice before anæsthesia, are liable, in individuals peculiarly susceptible to its action, to produce serious effects after the anæsthetic has been administered. It is for the same reason unwise to administer usual doses of morphine too soon after the anæsthesia.[1] Opium acts most satisfactorily when given subcutaneously two or three hours before the narcosis; its full effect is thus obtained a considerable time before the anæsthetic is administered, and nervousness and apprehension on the part of the patient are very materially lessened. The application of local anæsthetics to the air passages lessens considerably the irritating effects of ether; otherwise this measure is of questionable utility.

In 1876, Clover in England, demonstrated the fact that a very satisfactory anæsthesia resulted from the successive use of nitrous oxide and ether. Clover perfected an apparatus for the administration of these agents in conjunction with this form of anæsthesia, known as "gas and ether," which has been used to a considerable extent, particularly in England. Nitrous oxide is almost an ideal agent for the production of anæsthesia, though not for its maintenance. It is pleasant to inhale, rapid in its action, free from irritating or stimulating effects, and is the safest anæsthetic known. Used to precede ether, a form of etherization is obtained that is exceedingly satisfactory. The patient, at the beginning, is spared any knowledge of the ether used, none being administered till unconsciousness is present from gas. There are no coughing or choking, no "stage of excitement," and little or no mucus. When the ether is begun it can be pushed to complete anæsthesia within two or three minutes.

Apparatus.—Although the apparatus perfected by Clover and that by Hewitt are best adapted to this particular form of anæsthesia, it can be induced with very simple apparatus, a fact which adds greatly to the practicability of the method. The object of this paper is to call attention to this simple method of giving "gas and ether," to recommend it as a decided improvement over ordinary etherization, and to emphasize several points which are essential to its success. The plan being first to anæsthetize the patient with gas and then change to ether, it is necessary to have a gas and an ether inhaler. The gas inhalers supplied by the dental establishments are satisfactory, especially those having face pieces with inflatable rims. The best ether inhaler to use for this particular purpose is Ormsby's, for with it a very rapid ether anæsthesia can be brought about, and a rapid induction of ether anæsthesia is absolutely necessary to the success of this method of anæsthetizing. This is due to the fact that the gas anæsthesia passes off so quickly[2] that were the ether not pushed very rapidly the patient would come out in some degree, and the transition from gas to ether would be attended by some of the phenomena of incomplete etherization and possibly by some return of consciousness.

A fairly satisfactory substitute for Ormsby's inhaler may be made from the common cone with certain modifications. It should be made large, somewhat smaller at one end, both ends being left open.[3] The edge of the large end should be well padded with cotton in order that it may be closely adapted to the face.

[1] Hewitt ("Anæsthetics") points out this danger, and refers to cases of serious accidents and of deaths from this cause.

[2] One-half to one minute.

[3] Such a cone is represented by covering a long grass cuff with paper and towel.

In the smaller open end should be fixed a good-sized sponge. Over the smaller end of the cone a good-sized bag is now fitted, the common thin rubber ice bag answers the purpose; its opening being stretched over the end of the cone.[1] This practically converts the cone into a "close inhaler." A better substitute for Ormsby's inhaler may be made by utilizing the common metallic cone, which has a compartment screened off for holding the sponge. This should be fitted with a bag and an inflatable rubber face piece, such as is used with Ormsby's inhaler. This face piece may be obtained from any instrument dealer.

Technique.—In administering nitrous oxide, it is essential to a rapid and quiet anæsthesia that air should be totally excluded. All air should therefore be expelled from the bag of the gas apparatus before it is filled from the cylinder. The face piece should be accurately fitted, so as to prevent entrance of air at its edges, before allowing gas to be breathed. The respiration should be deeper and more forcible than normal. In about one minute the signs of complete nitrous-oxide anæsthesia will appear; the most important of these are an irregular, stertorous respiration, twitching movements in the extremities, and moderate cyanosis.

It is not necessary to push the gas after these signs first appear; in fact, it is undesirable to do so, for such a course will result in so stertorous and interrupted a form of respiration as to interfere with the intake of ether vapor. The gas should therefore be stopped and the administration of ether begun. In changing from gas to ether it is necessary that but little air be admitted. The average case should not be allowed more than one inspiration of air at this time. If Ormsby's inhaler is used, its air valve may usually be fully open when the inhaler is applied: but it is to be gradually closed as soon as the respiration tends to become regular and cyanosis begins to lessen. (If a modified cone, without air valve, is used, it need not be adapted to the face so closely at first as will be necessary when stertor and cyanosis lessen. The object to be attained is a gradual subsidence of the nitrous-oxide anæsthesia with a coincident rapid etherization.) The gas apparatus should be taken off during an expiration; air is allowed at the following inspiration; the next expiration should be caught in the ether inhaler and will serve to distend the bag. The change from gas to ether is to be made so quickly that it is necessary to have the ether inhaler charged and ready for use before it is needed. It may be prepared by the anæsthetizer before beginning the administration of gas or by an assistant during that procedure. About one ounce of ether should be poured upon the sponge,[2] and until it is used the inhaler should be placed with its open end uppermost and covered with a towel. This will prevent loss of ether vapor. Before ether is poured upon the sponge it should be wrung out of hot water.

At the first inspiration from the ether inhaler a strong ether vapor is presented to the patient and there will usually be some hesitation in the breathing at this point; in fact, the respiration for the next few seconds is usually rather unsatisfactory, it being spasmodic, jerky, and irregular. Not infrequently the breath is held so long that great cyanosis appears. The spasmodic respiration is that usually seen in complete gas anæsthesia, and it may be expected to subside within a few seconds as a result of the air given at the time of the change to ether. Should it not subside, however, and should the cyanosis increase, it will be necessary to allow another inspiration of air or several inspirations at intervals of a few seconds, till the respiration becomes regular and the cyanosis lessens. It occasionally happens that the stertor is so great that the respiration practically ceases, and it becomes necessary to open the mouth and pull the tongue forward. Instruments for this purpose should invariably be at hand. The holding of the breath after the first inspiration from the ether inhaler is occasionally of such long duration that it is necessary to remove the inhaler and possibly open the mouth; usually, however, a number of inspirations are held a short time, and respiration gradually becomes regular. Under these circumstances the inhaler should be kept closely applied till ether anæsthesia is complete, only enough air being admitted to prevent very marked cyanosis. Moderate cyanosis must be expected till ether anæsthesia is complete, when the admission of air will quickly remove it. Thus, in the first half-minute or more of the ether administration it may be necessary to allow three or four inspirations of air at intervals of five or ten seconds, the guide being the amount of asphyxiation present, as denoted by the cyanosis and stertor. Should these be moderate and decreasing, less air need be given; if marked and increasing, more air must be allowed. In this respect patients will differ greatly, and each must be conducted according to the indications present. Here a little experience and skill will enable the anæsthetizer to bring about a satisfactory transition from gas to ether in the majority of cases. The etherization is now continued as usual.

It is obvious that in the use of a "close" ether inhaler, *i.e.*, one provided with a bag for the re-breathing of air and ether vapor, some provision must be made for allowing fresh air. In Ormsby's apparatus there is an air valve for this purpose, and after the anæsthesia has been carried to a complete degree the valve may be opened half-way or more and kept there throughout. In using an inhaler having a tightly fitting face piece without an air valve, fresh air is to be admitted by removing the inhaler from the face several times a minute, allowing one or two inspirations of pure air at each removal. The amount of air and the frequency with which it is to be given will vary, depending upon the conditions present in each case. In general terms, a frail, weak patient must be allowed a considerable amount of air at short intervals, whereas a powerful, robust individual must have less air at longer intervals. As the anæsthesia proceeds more and more air may be allowed. It is rarely necessary to produce cyanosis by the use of a "close" ether inhaler. In adding ether to these inhalers after the initial dose, one or two drachms at a time will be found sufficient.

This form of "gas and ether" anæsthesia is practically that known in England as the method of Mr. Woodhouse Braine, and its chief recommendation is its simplicity. The advantages of "gas and ether" are obvious. Perhaps the greatest is the comfort to the patient. To be spared that period of etherization which precedes loss of consciousness is indeed a boon, and to be assured of this relieves the patient of much of the dread of the operation. Particularly is this so of patients who have been previously etherized in the usual way and of those who are particularly distressed by the first "whiffs" of ether, as are many nervous or hysterical subjects, those in great fear, those who become nauseated at the first smell of ether, and others. The rapid anæsthesia, absence of stage of excitement, and freedom from mucus are undoubted advantages. The amount of ether required is less than usual, hence recovery is somewhat more rapid

[1] In place of the rubber bag a common paper one may be used, being held in place by a strong rubber band, and this has the advantage that a new bag may be supplied for each patient.

[2] The sponge should be large enough to fit the upper part of the inhaler closely when wet. It should be somewhat coarse in texture to allow air to pass through it readily.

[1] Hewitt "Anæsthetics."

and after-sickness less. A trial of this method of anæsthetization in cases suitable for ether will demonstrate what Dudley Buxton[1] has said of it, *i.e.*, "It is the best method of producing general anæsthesia."

7 East Eighty-Seventh Street.

PARALYSIS: ITS FORMS, PROGNOSIS, AND TREATMENT.[2]

By EDWARD D. FISHER, M.D.,

PROFESSOR OF MENTAL AND NERVOUS DISEASE, NEW YORK UNIVERSITY, MEDICAL DEPARTMENT; ATTENDING PHYSICIAN, HOSPITAL FOR NERVOUS DISEASES, CITY HOSPITAL, ETC.

The question of the form of the paralysis should be the first to be considered in each case presenting itself for examination. The simplest and most practical division or classification is that based on the situation of the lesion or disease causing the paralysis. We may say, then, that there are four forms or types of paralysis based on this theory, *i.e.*, the cerebral, spinal, peripheral nerve, and intramuscular. The special symptoms always present in disease of these divisions of the nervous and muscular systems, especially the distribution of the paralysis and the trophic condition of the muscles affected in each, make the diagnosis usually an easy one.

With these explanatory remarks I will take up the first form of paralysis under our classification, *i.e.*, cerebral paralysis. The usual causes are hemorrhages, meningeal and intracerebral, thrombosis (due to atheroma of the cerebral vessels, usually the result of old age or chronic nephritis, or again to endarteritis syphilitica), embolism, tumors, injuries. One characteristic of the paralysis is the distribution, which in the majority of cases is unilateral, involving the lower half of the face only, with deflection of the tongue to the paralyzed side and paralysis of the upper and lower extremity of the same side. A second marked condition is the absence of any atrophy or wasting of the muscles (except long after from disuse). The muscles retain their tonus and remain firm; there is often rigidity or spasmodic contracture from the beginning, and this condition is always present later in the course of the disease, with exaggeration of the reflexes, *i.e.*, in the lower extremity; there is exaggerated patellar reflex and ankle clonus. Again, there are no changes in electrical reaction. There is always a normal response to both the faradic and galvanic currents.

This condition of paralysis without wasting, with the presence of increased myotatic irritability and normal electrical response, differs from all the other forms of paralysis referred to, and is due to disease of the motor or pyramidal fibres, which pass down from their origin in the cells of the cerebral cortex through the crus, pons, and medulla into the lateral column in the opposite side of the spinal cord. Any lesion of these pyramidal fibres, whether situated in the cortex, subcortical region, internal capsule, crus cerebri, pons, medulla, or lateral tract of the spinal cord, must give and can give only this so-called cerebral type of paralysis, *i.e.*, that form in which the muscles do not atrophy, present no electrical changes in reaction, and are subject to increased myotatic irritability.

We see from the above remarks that disease of the lateral tracts of the spinal cord, as in lateral sclerosis, gives us a cerebral type of paralysis. This is easily understood when we stop to consider that the tract involved in this spinal disease is essentially a cerebral tract of fibres which start from the brain in their course to the cord, receive their origin and nutrition in the cells of the cortex, and serve the muscles only in carrying the impulse or order of action from the brain to them. The muscles depend for their nutrition and growth only on the multipolar cells of the anterior horns of the spinal cord, conveyed to them through the anterior spinal nerves. The form of the paralysis, therefore, is the same wherever the pyramidal tract is diseased; the localization of the lesion depends on symptoms, the result of lesions involving other parts than this tract alone, and serve as landmarks as to the site of the lesion.

The second form to which I would direct your attention is the spinal type, and here I would refer only to disease of the anterior horns, for I have already placed paralysis from disease of the lateral tracts into our cerebral type. The usual causes of disease of the anterior horns of the spinal cord are inflammation, acute and chronic, hemorrhages, new growths, injuries, and compression, as in caries, spinal fracture, dislocation, etc. The special characteristics of this paralysis are atrophy or wasting; loss of tonus of the muscles, and therefore flaccidity; loss of reflexes; loss of response to the faradic current, and the reaction of degeneration to the galvanic current—always in acute disease, and at least decreased response to faradic and galvanic currents in the chronic forms, or a partial reaction of degeneration to galvanism with decrease or loss of faradic response; and, lastly, an absence of sensory disturbance—either anæsthesia or hyperæsthesia.

The most common forms of disease which give these characteristic symptoms are poliomyelitis, acute and chronic, and progressive muscular atrophy of the spinal type. These diseases have their own special etiology and course, which it is not my province at this time to go into, but they all have that character of paralysis, with wasting, electrical changes, and loss of myotatic irritability, which absolutely differentiates them from paralysis of cerebral origin. Again, in the spinal form the distribution of the paralysis—that is, the muscles affected—differs from that of the cerebral type, being usually bilateral, affecting both sides; or, again, involving only an upper or a lower extremity, or an upper extremity of one side with the lower of the opposite side; while, as I have said, in the cerebral form hemiplegia, or paralysis of one side, usually including the lower half of the face, is the common type.

In transverse myelitis we have both the spinal and the cerebral types of paralysis—that is, at the site of the lesion we have the muscles paralyzed, atrophied, flaccid, with loss of reflexes, and the characteristic changes of electrical response—*i.e.*, the spinal type; while below the lesion the paralyzed muscles do not waste, are rigid, have exaggerated reflexes, and present no electrical changes—*i.e.*, the cerebral type.

We will next consider our third form—the peripheral nerve paralyses. The usual causes are inflammation from diathetic blood states—as rheumatism, gout, etc.; or some micro-organism—as in diphtheria, typhoid, malaria, beriberi; or, again, some chemical or metallic poison—as alcohol, arsenic, lead, mercury, etc.; or, lastly, to injury resulting in compression, lacerations, or section of the nerve or nerves. The character of the paralysis is of the spinal type, *i.e.*, wasting, flaccidity, loss of reflexes, and electrical changes, but associated with it we usually have marked sensory symptoms, especially when the disease is acute in its onset. In acute inflammation of the peripheral spinal nerves there is always great pain on pressure along the course of the nerves, and also in the muscles supplied by these nerves. There is also subjective pain of a burning, gnawing character, almost more unendurable than true neuralgia. The most typical example of this is seen in acute alcoholic multiple neuritis. There is almost always also some disturb-

[1] Buxton: "Anæsthetics."

[2] A paper read before the Medical Society of the State of New York, at the ninety-second annual meeting, held in Albany, January 25–27, 1898.

ance of general sensation, showing itself in incomplete anæsthesia, paræsthesia, etc.

In chronic inflammation of the peripheral nerves, as more commonly observed in lead paralysis, the sensory disturbance is much less marked, often insufficient for the patient to observe it subjectively, although on careful examination it may be brought out objectively. When the nerve is destroyed, either by disease or by injury, of course the paralysis is always accompanied by complete loss of sensation of the parts supplied by it. This sensory disturbance is not present either in cerebral or in spinal paralysis, and is thus of great value as a diagnostic differential point, especially between anterior-horn disease in the spinal cord and peripheral-nerve paralysis.

In transverse myelitis, indeed, we have loss of sensation below the lesion in the spinal cord, due to disease of the sensory tract, but this sensory disturbance differs from that of the nerve lesion, in that on pressure there is no pain either in the muscles or in the nerves. This differential point is of the greatest importance often in our diagnosis between acute multiple neuritis and acute transverse myelitis.

The distribution of the paralysis in nerve lesions is also somewhat characteristic. A single nerve may be affected, as the musculo-spiral or facial, from either injury, rheumatism, gout, exposure, etc. Certain poisons, again, as that causing diphtheria, affect especially the throat and eye muscles, together with bilateral involvement of the upper and lower extremities. Again, lead involves the extensors, especially of the forearm and the muscles of the hand, only rarely affecting the lower extremities; while alcohol and arsenic first involve the lower extremities, giving double foot drop, and later as a rule pass to the upper extremities.

Our last form is intramuscular paralysis or so-called muscular dystrophy. This disease is rare as compared with those already referred to. Its cause is obscure, apparently due to some hereditary influence, and has its seat in some embryonal developmental defect. It is observed often in various members of the same family or in collateral branches. Resembling as it does progressive muscular atrophy, it might properly be termed hereditary progressive muscular atrophy with as much appropriateness as we speak of hereditary ataxia. Here the paralysis is of the spinal type, resembling, as we have said, spinal progressive muscular atrophy—*i.e.*, the muscles are wasted, although they may at first appear hypertrophied from fatty infiltration of the muscle fibres and at times actual enlargement of individual muscle fibres; ultimately with time the wasting becomes extreme. There are also flaccidity, loss of reflexes, and electrical changes, characterized by decreased response to faradism and partial reaction of degeneration. Instances of this disease are pseudo-hypotrophic paralysis, Erb's scapulo-humeral type, etc. This form of paralysis is also distinguished by the distribution of the paralysis—in one form affecting especially the legs, in another the upper arms and thighs, or again associating with this the face, giving us then the so-called facio-scapulo-humeral type. Their distribution, their hereditary character, and their occurrence in youth sufficiently diagnosticate them.

Prognosis.—In cerebral paralysis, if the pyramidal tract has been destroyed in any part of its course, recovery is impossible; restoration of nerve fibres in these tracts after their destruction never takes place, as has been proven experimentally and demonstrated by pathology. Paralysis resulting from compression only, as in Pott's disease, etc., even when of long duration, may be entirely recovered from. The prognosis is therefore unfavorable as a rule, as in most cases of cerebral apoplexy the lesion is more or less a destructive one.

Acute spinal paralysis due to affection of the anterior horns is also rarely recovered from. Here again, as also is usually the case, there has been an actual destruction of nerve structure, *i.e.*, the nerve cells, and they can never be restored. As a rule, one or more extremities remain atrophied and paralyzed. Chronic or subacute poliomyelitis is much more likely to be arrested in its course and recovery occur.

Degenerative disease of the anterior horns or progressive muscular atrophy is incurable, although there may be by appropriate treatment much delay in its usual progressive course.

Transverse myelitis, in what may be called favorable cases, is usually recovered from with evidence of a more or less marked condition of spastic paraplegia.

Peripheral nerve paralyses are usually recovered from; the outlook is more favorable than in any of the other forms of paralysis.

Muscular dystrophies are also progressively unfavorable. A few patients have been reported as having recovered, at least partially, under careful massage, electricity, and exercise: but this is certainly the exception.

Treatment.—While on the whole the prognosis is unfavorable as to recovery in these various forms of paralysis, with the exception of peripheral nerve lesions, still much can be done either to alleviate the existing conditions or to stay the progress of the disease. In the cerebral type the rigidity and contractures of the muscles can be lessened by massage and electricity, and the form most favorable is the galvanic current, as often faradism may stimulate or irritate the muscles to increased contraction. Hydrotherapy, especially as carried out in some of the institutions at the various springs—as Virginia Hot Springs, Richfield—is very useful. In poliomyelitis the treatment of the paralyzed muscles should be long persisted in. Even a year after the onset, by manipulation of the individual muscles and electricity applied in the same particular manner, much can be accomplished; also apparatus devised to exercise the various muscles should be employed, or when possible the bicycle should be recommended. Deformities should be guarded against by appropriate apparatus. In the case of a child this should be made as light as possible, so as not to interfere with ordinary exercise. I have often seen appliances so heavy or inconvenient that they retarded rather than aided attempts at locomotion. Patience is required in this disease, and while we cannot usually hope to cure, we can accomplish much in cases of not too severe a type, which, if left to themselves, would rapidly pass into hopeless deformity. Certainly in chronic poliomyelitis the above treatment faithfully followed out is often successful. Even in the degenerative and hereditary forms of paralysis this care is of benefit. In peripheral nerve lesions, as soon as the acute stage is passed, massage and electricity are of great value. I agree with many writers that probably the electricity has little if any influence in removing the disease in the nerve itself, but, as these diseases have a tendency to recovery, we are thus enabled to maintain the muscle in a good state of nutrition and prevent deformities, so that they are ready to respond to the nerve when the inflammatory process has subsided. The benefit of electricity in this disease cannot be denied, according to my experience; therefore, whatever its principle of action may be, it should be employed. I have not spoken of drugs in this connection, as my paper was not intended to take up that division of the subject. However, in all these forms of paralysis, with the exception of the cerebral type, strychnine is certainly of advantage.

The doctor who welcomes the sample man takes his last chance of making a show of business in his office.

WASHING THE BLOOD IN ACUTE URÆMIA.

By CHARLES E. NAMMACK, M.D.,

VISITING PHYSICIAN, BELLEVUE HOSPITAL; CONSULTING PHYSICIAN, GOUVERNEUR HOSPITAL, NEW YORK.

Uræmia is a condition dependent upon the retention in the blood of waste products that should be cast out by the kidneys. When the accumulation of these toxic products has been very rapid, the nerve centres are excited into explosions of nervous energy which are clinically manifested by convulsions. No emergency of general practice needs to be more promptly met, and in none has the therapeutical handling hitherto been more unsatisfactory. Failure to relieve acute uræmia has been partly due to the former belief that it was invariably the result of a single cause, whereas it is now known that the poisons producing the condition are many and that these may be produced by widely differing causes. This has been demonstrated by the careful work of Bouchard, and, in our own country, of Christian A. Herter. The object of this brief paper is not to discuss theories, but to point out a measure of value when the condition of acute uræmia confronts us. And here we must discriminate between the acute nephritis with resulting uræmia which occurs as a part of an acute infectious disease and which depends upon the infecting agent, and the acute exacerbation of uræmia occurring in the course of chronic nephritis. These latter cases are frequent in city life and in hospital practice, and to them is especially applicable the procedure herein advocated. The patients may present the usual premonitory symptoms of Bright's disease, or, without warning, convulsions may determine the occasion of the physician's first contact with the case. The convulsions may be followed by coma, or, instead of coma, violent and active delirium may occur between successive attacks of convulsions. Many cases are mistaken for epilepsy, and in all the differentiation requires careful study. This study is important, because the prognosis in acute uræmia depends upon the ease and rapidity with which the toxic principles may be eliminated by the system. In this elimination all the excretory organs must take part, but the amount that can be carried out through the skin and bowels by the action of drugs, hot air, and hot packs is so small as to render dependence on these channels unsafe in the face of impending repetition of convulsions. Chloroform usually controls the convulsions, but is disastrous to the patient. Morphine hypodermatically was warmly commended by the late Dr. Loomis and, under the influence of his teachings, largely used, but it is a treacherous drug in cirrhotic kidneys, and small doses will sometimes have a poisonous effect. Exacerbations of acute uræmia occurring in the course of chronic nephritis often happen when the patient feels unusually well and has indulged freely in flesh meat or alcohol, thus adding an acute toxæmia to the already existing blood deterioration. In these cases, blood letting to the extent of one or two pints followed by the injection of decinormal saline solution directly into the blood current, or into the subcutaneous tissues, or, when sterilization of apparatus cannot be depended upon, into the rectum, will give rapid and striking benefit. In the fourth medical division of Bellevue Hospital and in the Gouverneur Hospital, this is now the routine procedure, and it seems to the writer to be a marked advance over the older methods. It is simple, rational, and efficient, but is not applicable to old exhausted subjects in the terminal stage of chronic nephritis. Recent medical literature bears abundant testimony to its efficacy. Prof. Albert Robin is cited, in the Paris letter to the MEDICAL RECORD, January 15, 1898, page 103, as having treated cases with good results. The Philadelphia *Medical Journal* of January 8, 1898, has an editorial observation on page 57 commending it.

John Van Rensselaer[1] in a paper read before a medical society of Washington, D. C., called attention to the value of venesection and saline infusion in cases treated at the New York House of Relief.

Hughes and Carter,[2] in their Boylston prize essay for 1893, make a study of uræmia and state that free venesection cannot be too highly recommended, as either an abortive or a curative measure in grave uræmia. They further state that even a pronouncedly weak pulse will in no wise forbid its employment, as they have repeatedly seen the pulse strengthen while the blood was flowing. They also urge strongly that the bleeding be supplemented by transfusion of a decinormal saline solution.

J. W. Hoff[3] has had uniformly good results, in fifty years' practice, from venesection in eclampsia, as well as in other diseases.

F. W. Todd[4] commends Hoff's paper, and adds a successful case of puerperal eclampsia in a moribund woman.

C. A. Murray[5] believes that there is no other rational treatment for puerperal eclampsia.

Richardière,[6] in two cases of uræmia, removed blood and introduced double the quantity of Hayem's artificial serum with good results.

A. Albu[7] has very often seen the symptoms of acute uræmia disappear after blood letting, but cautions against its use in old cases of contracted kidneys with coexisting asthenia.

Nothnagel,[8] on the other hand, thinks that little can be accomplished by it except when the arterial pressure is very high.

T. H. Thompson[9] says that, although almost universally mentioned in text-books, blood letting in uræmia is rarely resorted to by the modern practitioner. Thompson cites a case in which he believes that it saved a man's life.

F. O. Yost[10] accords venesection high rank as a means of removing the cause of the attack.

D. L. Beckingsale[11] records the sensible conviction that the progress of medicine does not depend solely on discoveries in bacteriology, toxins, and chemical therapeutics, but also on culling from the experience of the illustrious dead and assimilating all that is worthy and reliable. He hopes that blood letting will reassert its proper position as a remedial agent.

T. K. Clarke[12] does not remember to have lost a case of puerperal eclampsia since he began to treat that condition by venesection.

William M. Holladay[13] says that in that dreadful disease, puerperal eclampsia, blood letting is a remedy by no means to be despised. He has treated eight cases and saved eight mothers and six children.

George C. Laws[14] makes a plea for venesection, which he believes to be the most prompt and efficacious remedy at our command in puerperal and uræmic convulsions. He deplores that therapeutic pessimism which considers it a mark of a weak intellect to believe in anything our forefathers held to be true, before the days when the schizomycetes and microbes began to hold sway.

Progress of Medical Science.

Treatment of Rectal Carcinoma.—The high position of a tumor is of itself no contraindication for operation (P. Kraske, Volkmann's "Sammlung klinischer Vorträge," May, 1897). If there are firm adhesions, the operation may be difficult or impossible; and if the growth is firmly adherent to the uterus, bladder, or pelvic bones, it should be pronounced impossible. The age, the resisting power of the patient, co-existing diseases, and metastases should be considered when deciding the question of operation. Before operation the bowels should be completely emptied by purgatives and enemata. This is a factor essential for the success of the operation, and to determine this one should resort to abdominal palpation, but more especially to urinary examination. Kast and Baas showed that the presence of ethyl-sulphuric acid in the urine decided this question. If a marked stenosis exists and it is impossible to empty the bowel completely, a preliminary temporary colotomy should be considered; if it should be deemed necessary, it should be done at least one or two weeks in advance. The best site at which to establish this artificial anus is at the transverse colon and not at the sigmoid flexure. The operation for the extirpation of the growth itself depends upon its size, seat, and extent. Growths that occupy the lower segment of the rectum offer but little difficulty in their removal. The incision should be made in thoroughly healthy tissue, allowing a large margin around the tumor, for it is neglect of this precaution that is often responsible for recurrences. If the whole circumference of the rectum is involved, a formal amputation may be required. In those cases in which the tumor reaches to the anterior layer of the peritoneum, anal and perineal and sacral incision is the method recommended. When the growth is highly situated and does not involve the lower end of the rectum, the method which attains a removal of the growth with preservation of function is resection of the rectum by the sacral method. This method includes three steps: (1) the preliminary operation on the sacrum; (2) the resectio recti; (3) the treatment of the peritoneum, the free end of the bowel, and the wound. The writer gives a detailed description of his method of procedure in the removal of the sacrum, which, in the essential points, conforms with his original views. He adopts one modification, which is a curved incision through the soft parts instead of the median incision. He condemns the osteoplastic method, in which the bone and soft parts are included in the flap; in its place Kraske adopts a procedure which is a resection of the left ala of the sacrum and a temporary exarticulation of the coccyx. He next details the resection of the rectum. To close the peritoneal opening he resorts to gauze tampons and not to sutures; the increased amount of time required for the application of sutures he considers a serious objection. In order to preserve the complete functional power of the sphincter the resection of only the malignant segment is preferred. He next considers the treatment of the cut section of the bowel. He believes that every attempt should be made to obtain union by the first intention, and to attain this end the whole circumference of the gut is sutured. In treating the external wound in order to avoid ulceration, he uses tampons of iodoform gauze, carefully introduced, which should be allowed to remain in for at least a week, after which the dressings should be changed more frequently. That the mortality has been higher since the sacral method was introduced the writer attributes to the fact that more difficult cases are now undertaken than heretofore. Comparing the author's series during the first five years, which he considers the experimental period, and those of the later seven years, the mortality has dropped from 34 per cent. to 9.8 per cent. Of the author's eighty operative cases fifteen resulted fatally, a mortality of 18.7 per cent. In eight of these cases of death not one was due to this operation in particular, but death might have followed any operative procedure. This gives seven cases in which death could be attributed to the operation, and reduces the mortality to 8.72 per cent. for the entire period; and for the series of fifty-one operations in the last seven years to 3.9 per cent. The cause of death in four of the above cases was peritonitis, brought on by a premature bowel movement occurring in the course of the first post-operative day. Four cases of mixed infection of bacillus coli communis and streptococcus occurred, three of them terminating fatally. The most frequent complication of this operation was cystitis, attributed to the use of catheters, which are always required. In regard to the permanent results of the operation, the writer traced all but five of his cases. Of these cases twenty-two were fatal from recurrence in from six months to twelve and three-fourths years after operation; sixteen were fatal from intercurrent affections without recurrence or metastasis; fifteen patients lived without recurrence for periods varying from nine months to eight and one-half years.

Hemorrhages in the Newborn.—According to Orlowski (*La Médecine Moderne*, August 25, 1897), hemorrhages in the newborn are more frequent than statistics would lead us to suppose. From November, 1895, to November, 1896, the writer saw thirteen cases of hemorrhage in fifteen hundred and twenty accouchements, or a proportion of one in one hundred and sixteen births. In one-fourth of the cases hæmatemesis and melæna were united; Kling, Silbermann, Lederer, and Dusser have observed the same fact. The melæna alone is not so rare as Grynfelf holds, since he represents the latter to be in the proportion of three to one of hæmatemesis alone. Umbilical hemorrhages are most frequent. These accidents appear ordinarily about the third day after birth; ten out of fifty-one cases noted by Silbermann showed themselves on the eleventh day, but these were cases of infection. Infection and syphilis are the two great causes of these hemorrhages; macroscopical, histological, and bacteriological examinations agree on these points. In the order of frequency the infectious agents encountered are streptococci, staphylococci, and colon bacilli. These micro-organisms cause hemorrhage in robust infants free from hereditary taint, as well as in the debilitated or syphilitic. It remains to be shown that the mother was infected by the same microbe that is found in the blood or organs of the child affected with hemorrhage. Negligence in ligating the cord is often the starting-point of the septicæmia. Hæmophilia is very rare, if one considers only the hereditary origin. The trouble may be caused by these micro-organisms being brought into the placental circulation by a tedious labor, by the passage of a head into a retracted pelvis, by the forceps injuring the vasomotor centres of the stomach, the intestines, and the lungs. The congestion set up by these means becomes a source of hemorrhage in these cases. The prognosis is very grave when the hemorrhage has lasted more than twenty-four hours. When it is accompanied by a serious infectious state, the constitution of the child

is of little account; the case usually ends fatally in spite of everything. The mortality is 85.8 per cent. When the hemorrhage is from the umbilicus, we should begin by loosening the dressings and trying different methods of ligature, but in some cases these all seem to be absolutely useless. In cases of gastro-intestinal hemorrhage the infant should be placed in an incubator with a temperature of 37° C., or in warm cotton. Three times daily it should have mustard baths, followed by friction with alcohol, hot baths, hot-water bags to the abdomen, hot whiskey, and subcutaneous injections of a solution of chloride of sodium, 7 to 100, doses of ten to fifteen grams repeated four or five times daily.

Colpotomy and the Surgical Treatment of Pelvic Peritonitis.—Dr. A. Martin (*Monatsschrift für Geburtshilfe und Gynäkologie*, Bd. vi., Heft 3) discusses the clinical symptoms and the pathological anatomy of pelvic peritonitis, with its associated diseases of the uterus and its appendages. In acute pelvic peritonitis the writer lays great stress on antiphlogistic remedies, particularly rest in bed. In chronic pelvic peritonitis, methods for absorption of the exudate should first be tried; should these fail, then only should operative procedure be thought of. For the worst cases a radical operation is the recognized and proper course of treatment; in the great majority of cases, however, only a conservative operation is necessary. This conservatism lies in the tearing and dividing of adhesions, and in the isolation of the individual pelvic organs; new adhesions are prevented from forming by the fixation of the uterus. Formerly ventral fixation was the only method at our command, and even now this operation is preferable in cases with extensive adhesions and in those in which the adnexa form large and degenerated tumors; in all others, based on an experience of four hundred and seventy-one cases with four deaths, of which two were from pyosalpinx, Dr. Martin recommends anterior colpotomy. The results of the latter operation are very satisfactory. Of the four hundred and seventy-one above-mentioned cases, eighteen became pregnant. In nine births, the delivery was hindered in two cases by the antefixation, yet in both, by the aid of version, the women were delivered of living children.

Hydrophobia and Common Sense.—Dr. George Ardin Stockwell, in a lengthy article on this subject (*Dominion Medical Monthly and Ontario Medical Journal*, December, 1897), concludes with a few simple axioms, which, if heeded, will, he thinks, in the majority of cases allay fear and quell the senseless epidemics of rabiphobia that threaten from time to time. 1. Rabid dogs do not fear but court water. 2. Rabies can never arise spontaneously either in animals or man. The absence of recent wounds upon and the good health of the creature inflicting the bite are alike evidence of the non-specific character of the disease. 3. Wounds inflicted by the teeth of non-carnivorous creatures are never rabic, though a blood poisoning may be induced. Man cannot communicate the disease to other human beings or to animals. 4. The saliva of truly rabid carnivora alone is capable of inducing rabies. 5. Excessive saliva in any creature, more especially dogs, is always induced by any affection of the mouth or throat; is the universal sequel of toothache, of inability to swallow from any cause, of paralysis, of throat abscess. Paralysis independent of rabic condition is a sequel to numerous local brain and nerve maladies; twitching of eyes, of eyelids, of lips, and muscles, lolling tongue, indrawn tail, upward flanks, drooping head, slinking gait—one and all should be included in the same category. 6. Safety lies in preserving the life of the suspected canine and sequestrating for observation; by premature death the only evidence whereby rabies can definitely and with certainty be established is destroyed. Muzzle the creature and examine for recent wounds; if none is exhibited, fear is idle: if it evinces a good appetite and if it partakes of food freely on and after the fourth day, it is not rabid; if it dies without paralysis, it is not rabid; if it succumbs to paralysis, the chances are still a thousand to one its death was due to some natural cause; if it falls into convulsions and froths at the mouth, it is an epileptic and an object of commiseration. Ninety-nine out of every hundred dogs pronounced "mad" are epileptics or choreics, and dogs with "fits" are positively never rabid; if after ten days' confinement the suspected animal evinces a cheerful disposition, there is no danger whatever and it should be released. When death supervenes, critical examination of the body—the brain, viscera, etc.—should be made by a competent pathologist, to determine whether there is a cause for death aside from rabies. 7. Members of the human race, suffering from rabies, do not howl, whine, bark, or exhibit other canine characteristics or peculiarities, any more than do cats, fowls, sheep, cattle, etc.; such phenomena are conclusive evidence the malady is—hysterical. 8. Intolerance of light and air in motion, fear of water and bright substances, and spasm of muscles of the throat and neck, far from constituting specific evidence, are common in diphtheria, croup, goitre, sore throat, lockjaw, pregnancy, hysterics, ear abscess, hay fever, poisoning by certain mineral and vegetable substances; they may arise from the use of narcotics, sedatives, and alcoholics; from cancerous affections, certain maladies of the internal ear, or of the eye as in glaucoma, diseases peculiar to sex, and a multitude of brain and nerve maladies. In no instance would these symptoms excite special comment or alarm were not the dog linked therewith as a factor. 9. Error in judgment is the almost inevitable result of accepting mere negations for their anthesis. Careful examination of the evidence laid down for the distinction of rabies reveals little aside from mere negations. Until death ensues the weight of evidence is always negative; when dissolution follows it is very far from being presumptive of the positive. 10. Since less than three per cent. of infected canines ever contract the malady, the danger to man is several hundred times less than from scarlatina, measles, quinsy, ague, and a host of simple maladies. As Prof. Charles Bell Taylor remarks: "It is less than one in a million—less than being kicked to death by a horse;" to which may be added, it is less than the gallows. Atop of all, it may be said that, after examining as thoroughly as possible the history of every case of rabies reported as occurring in North America during fifty-five years (and they number about one thousand), I have been unable to find even one that was not open to the gravest suspicion as to error.

Animal Disease Communicable to Man.—Dr. Charles Gresswell, in the *Colorado Medical Journal*, December, 1897, concludes an able article on this subject with a brief *résumé* of the results of late researches into this subject: 1. Koch claims to have established the unity of the tubercle bacillus in all animals, including man, but Maffuci claims that a difference exists between that of mammals and that of birds, the latter being less virulent than the former. Kruse gives the histories of four varieties, and Pansini concludes that transition forms exist. Experimental research so far has not established sufficient differentiation of the tubercle bacillus (in spite of its well-known character of being highly specialized toward an intracellular existence as a parasitic organism) to lead to the hope that it cannot take root in all mammals alike under

similar conditions. Other microbes, such as that of Texas fever, are so specialized as to be harmless to other animals than cattle, and it may be that that of tubercle will prove to be of a varying degree of virulence as between animals and man, but at present we must accept the conclusions of Koch. 2. The raw milk of tuberculous cattle, even if the disease is localized and not general, will communicate the disease to all other susceptible mammals. The flesh of tuberculous cattle is contagious when the disease is general, not when localized. The flesh of tuberculous swine is infective generally, on account of the greater liability in the hog to general tuberculosis. The milk and flesh of both are harmless if properly cooked, boiled, or sterilized. 3. Many thousands of illustrations are now on record, proving that the tuberculin test is extremely accurate in diagnosis of even the slightest presence of tuberculosis, and that it is harmless to healthy animals. 4. Although the conditions of susceptibility are hereditary, the young of tuberculous animals are born free from the disease, and can be raised apart from their mothers without necessary contraction of the disease. 5. Susceptibility is much increased by inbreeding or intense breeding from varieties for one result, by close confinement, by impure air, and by any condition or sets of conditions which lower the general vitality of the system. 6. Where conditions exist tending to increased susceptibility, the germ itself increases in its contagious virulence as it spreads from one animal to another of those under such conditions, and this to such an extent that an ordinarily immune animal is likely to succumb when brought into immediate contact with the germ so increased in virulence. 7. The susceptibility of inbred stock can be remedied by suitable outcrossing, and the same is true, but less marked, of intensely bred animals. 8. A system of semiannual tests with tuberculin, isolation of affected animals to be kept for breeding purposes only, condemnation of all showing physical signs of the disease, strict attention to improved sanitary conditions and methods of breeding, has been found effectual in stamping out the disease among cattle. 9. Considering the great susceptibility of so many of the human family by reason of their faulty environments, and in healthy men immediately after recovery from other germ diseases, and in children generally after attacks of the infantile fevers of nutrition, all milk derived from herds which have not been submitted to the tuberculin test should be sterilized or boiled, and all meat from animals with general tuberculosis should be condemned. 10. It is a grave question as to how far the expense of the tuberculin test, and that of the occasional condemnation, should fall upon the dairy owner or upon the public; for it is hardly fair that a higher standard of purity of food products should be expected from the milk vendor than from the butcher who sells ptomains with his meat, from the saloon keeper who sells fusel oil with his whiskey, or from the druggist who vends unknown patent medicines for the cure of unknown diseases—all of whom may be said to be guilty of occasionally poisoning the public as well as is the dairyman who unwittingly sells the seeds of consumption with his milk.

The Diagnosis of Diphtheritic Angina.—Dr. Guillemaut (*La Médecine Moderne*, August 25, 1897) says that the diagnosis of diphtheritic angina based on clinical phenomena still holds its place in practice. He sets forth the actual difficulties of the bacteriological diagnosis of diphtheria. The bacilli of Loeffler, in all forms and of all degrees of virulence, are found in many healthy throats; generally the bacilli are not active, but in certain conditions they may become virulent. Dr. Haushalter said, at the congress of Nancy, that simple anginas with the bacilli of Loeffler do not differ clinically from those without these bacilli; these anginas ought to be regarded as diphtheria. When one finds in membranous diphtheritic anginas only the short bacilli, the pathogenic rôle of which is very doubtful, one ought to hesitate before using the serum; they may indicate only a laryngitis. One cannot base a prognosis on the form and number of bacilli observed on the culture; the clinical signs furnish the best indication, as the procedure necessary to distinguish the true Loeffler from the pseudo-bacillus has not yet been simplified. In many instances the clinical examination alone will suffice as an indication for the serum treatment, and by adopting it at once we gain the twenty-four hours that the bacteriological examination would otherwise consume. There are still too many contradictory opinions relative to the prognostic value of the microbic association in diphtheria for the clinician to be able to draw profitable information from the bacteriological investigations made on this subject.

Spontaneous Rupture of the uterus before term must certainly be very rare, and I find only one instance recorded. A case is recorded in the *British Medical and Surgical Journal*, 1858, p. 847, due to tuberculous degeneration. Some writers declare that it can be caused by carcinoma; several early writers report instances of rupture in the early months of pregnancy, but always in the cornua of the uterus, and such instances are open to the suspicion of extra-uterine pregnancy.—Dr. Harold Metcalf, *Atlantic Medical Weekly*, December 25, 1897.

On the Treatment of Epilepsy.—Dr. Paul Flechsig (*Neurol. Centralblatt*, No. 2, 1897) states that, by his bromide-opium method of treatment, in a series of fifty cases, he has had six excellent results with cessation of attacks for two and one-fourth years. All the patients presented the following: (1) long duration of the disease, some even twenty years; (2) other treatment, and particularly by bromides, has been without avail; (3) all kinds of psychical phenomena were present, such as weak memory, lack of nerve tone, irritability, morbid fear; (4) a "torpid" constitution, generally with anæmia. As a rule, he does not begin with the combined opium and bromides treatment, except in those cases in which the disease has apparently developed through fear, sorrow, etc.; but starts with the ordinary bromide treatment. He uses the opium when bromides do not affect the disease, when bromidism begins, etc. The reasons for the good results of this treatment are as yet not positively known. The writer regards diet, rest in bed, rectal enemata, etc., as important accessories to the treatment. It may be that the opium produces its good effects in overcoming the nervous irritability and the causeless fear of these patients, for most epileptics are psychically perturbed. The patients must be treated as if quite ill, *i.e.*, they must be under the continued observation of the physician and of a reliable nurse.

Bacteria in the Normal Conjunctiva.—In a study of the effects of aseptic and antiseptic irrigations in eye work, Dr. Robert L. Randolph (*Archives of Ophth.*, vol. xxvi., No. 3, 1897) draws the following conclusions: 1. The normal conjunctiva always contains bacteria. Of these the staphylococcus epidermis albus is found with such frequency that it must be regarded as a regular inhabitant of this situation. This coccus and probably other bacteria found in this locality are usually of only slight if any pathogenic power. It should be remembered, though, that bacteria ordinarily non-pathogenic may become harmful under certain favoring conditions, such as the bruising of the tissues by instruments or the irritation resulting from chemical substances. 2. Neither the irrigation with sterilized water nor the instillation of a sublimate so-

lution (1 to 5,000) produces sterility of the conjunctiva, and inasmuch as both measures are futile and possibly harmful they may just as well be abandoned. These methods of sterilizing the conjunctiva are the ones usually employed by ophthalmologists, and hence the choice of them for testing this question. The most important essential of a germicide which is to be used upon the conjunctiva is that it be absolutely free of irritating properties, and, furthermore, it should be demonstrable that this germicide will destroy the germs most commonly met with in the normal conjunctiva. It goes without saying that an antiseptic which has these qualities would be indispensable in all operations on the eye. 3. In operating upon the normal conjunctiva, as in cataract operations, the surgeon in the present state of our disinfecting armamentarium would do well to consider the subject of antisepsis and asepsis chiefly, if not solely, in connection with the hands, instruments, cocaine, and atropine.

Intestinal Features of Typhoid Fever.—In the first number of the *Philadelphia Medical Journal* is an article by Dr. William Osler, on "Some of the Intestinal Features of Typhoid Fever," which is deserving of a careful study. Anything from the pen of Dr. Osler is always worth reading, but at the present time the subject of typhoid fever possesses exceptional interest. This is so not only on account of the devastating epidemics of this disease which have prevailed in England during the last few months, but also because the fact has been increasingly forced upon us that our knowledge in respect to many of its features is defective or wholly erroneous. Regarding typhoid from the bacteriological point of view, although the advance in demonstrating the widespread nature of its infection has been most striking, yet even in this relation there is still much to be learned. It is, however, in the insufficient knowledge of the disease itself that our ignorance is most marked. As Dr. Osler points out, until a comparatively recent period typhoid fever without intestinal lesions was not recognized as such, and he now further states that he has in the past year met with a case in which there was a general infection without involvement of the lymphatic tissues of the intestine. Nevertheless the belief appears to be steadily gaining ground that the intestine is wholly the seat of the disease, and, in consequence, the method of treatment pursued is by means of purgatives and antiseptics. Dr. Osler emphatically dissents from this view; he claims that the disease is of a systemic rather than an enteric nature, and is opposed to the use of purgatives except when absolutely indicated. When such is the case castor oil is recommended, but the use of intestinal antiseptics or salts is never advised.

Removal of the Whole of the Bowel of a Child below the Transverse Colon.—Mr. Frederic Treves, senior surgeon to the London Hospital, has for the first time in the annals of surgery performed this radical operation. The history of the case, as reported in *The Lancet*, is briefly as follows: A little girl, aged five years and nine months, was brought to him on January 5, 1897. She was the daughter of perfectly healthy parents. She was suffering from extreme constipation, which was attended by frequent attacks of intestinal obstruction. The abdomen was of enormous size, and was distended like a balloon. It was everywhere uniformly tympanitic. Through the thin parietes an enormous coil of intestine, evidently the colon, could be seen. Mr. Treves, on January 13, 1897, performed laparotomy. There immediately presented a gigantic coil of the colon, which looked and felt like the adult stomach, and which appeared to fill up the whole of the abdomen. The wall of this intestine was smooth and much thickened by hypertrophy, and the actual diameter of the collapsed loop was eight inches. After passing a gum-elastic tube of large calibre through the anus into the interior of the dilated bowel with unsatisfactory results, an artificial anus was established in the centre of the median wound, and for nine months all motions were passed by this opening. In October, owing to the great difficulty met with in keeping this artificial anus open, Mr. Treves determined to attempt the excision of the colon from the splenic flexure to the anus. The second operation was performed on October 29th. By means of an elliptical incision in the skin, the artificial anus was isolated and removed, and the abdomen entered on each side of the opening. The orifice in the colon was closed by a series of substantial sutures. It was found that the gut, which had at one time been so enormously distended, was now of more moderate dimensions. The dilation of the colon extended up to the splenic flexure. Beyond that point the colon was practically normal, although it had evidently been to some degree distended and still showed some hypertrophy of its walls. The colon on the right side was normal, and the whole of the greater bowel had a very free mesocolon. Having found that the left extremity of the transverse colon could be brought to the anus, the left colic artery was isolated and ligatured, and the bowel, after being clamped, was divided at the splenic flexure. The sigmoid artery was then isolated and the superior hemorrhoidals were isolated and ligatured. The gut, representing the descending colon, the sigmoid flexure, and the upper part of the rectum, was then excised and the bowel was divided low down in the pelvis, below the entrance of the superior hemorrhoidal artery. The child was now placed in the laparotomy position, and, an elliptical incision having been made around the evidently narrowed anus, the anus, together with the lower and remaining portion of the rectum, was removed. The separation of the rectum from the slender vagina was a tedious matter. The middle hemorrhoidal vessels were secured and the lower end of the rectum was removed without difficulty. The transverse colon was then brought down to the anus, where it was secured by a series of close sutures. The gut was conducted into position by four pressure forceps, which were passed into the abdomen through the hole in the perineum. The operation was concluded by closing the wound in the abdomen without drainage. The child made an excellent and speedy recovery. No sedative of any kind was needed, as little pain was complained of. The only complication was represented by some suppuration between the new rectum and the vagina. As soon as the child began to run about, this discharge ceased entirely.

The Serum Diagnosis of Typhoid Fever.—Dr. Fernand Widal (*British Medical Journal*, December 18, 1897) sums up as follows: "From the practical point of view, the reaction can in general be detected in typhoid patients from the first days of the disease onward; it may at times be delayed, but is only exceptionally absent (one case in one hundred and seventy-seven, according to my figures). One can hardly expect more from a method based on a biological reaction always subject to individual and unforeseen variations."

Theories of Post-Mortem Delivery.—Two explanations have been advanced: the first supposes that the pressure produced in the abdomen by the gases evolved in post-mortem decomposition is sufficient to cause the expulsion of the uterine contents, while the second suggests that the necessary force is brought about by the condition of rigor mortis into which the muscular structure of the womb is thrown.—Bleich, *Lancet*, December 18, 1897.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 26, 1898.

THE HEALTH-BOARD BILL.

WE have been greatly surprised at some of the objections that have been raised against Senator Brush's bill amending the health-board bill. It has been asserted by opponents of the bill that the amendments to section 1,247 restricted the powers of the board in dealing with contagious diseases. Such was not the fact. The amendment in question gave direct legislative authority requiring that certain diseases should be reported, while section 1,172 permitted the addition of such others as the health board might see fit to designate. If the opponents of this bill had searched the charter a little more carefully, they would have found in chapter 47 that the municipal assembly has power further to regulate health ordinances, and could in its pleasure even add a few more diseases that the physician would be obliged to report. The amendments in the Brush bill, then, in no wise detracted from the power of the health board to exercise increased and direct authority.

We presume that the various medical boards of hospitals which have been "resolving" on this subjecet were not aware of these facts, but we are astonished that the agitators who are in opposition to the bill had not acquainted themselves more fully with the various provisions of the charter.

Objection has also been made to the bill because it repeals section 1,226 of the charter. This section is virtually a reprint of one of the session laws of 1895, permitting the health board to sell a surplus of the productions of its laboratories. This the board has been doing since that time, and it is to this we objected —first, on the ground that the municipality should not engage in private merchandising enterprises; and, secondly, because we are credibly informed that, while these sales have been made to apothecaries in this city at the net profit of one dollar a vial, the price has for distant cities been made as low as fifty cents and perhaps less. We are also informed that the late board further violated at least the spirit of the law by making advance sales of antitoxin before the same had been actually prepared. If we are in error in regard to either of these statements, we shall be glad to receive an authoritative denial. Will any of our readers defend these practices? The opponents of the bill tell us that the repeal of section 1,226 will absolutely forbid the sale of antitoxin by the health board. Evidently these gentlemen are ignorant of the existence of section 1,553 of the charter, under the authority of which sales can be continued, but they would have to be open and above board and not by secret contract.

Perhaps it will comfort the opponents of the bill to know that it has been revised and now appears as senate bill 435, and that the amendments to section 1,247 have been omitted, leaving this section of the charter without change, and also leaving the health board with perhaps less power to combat contagious disease than the Brush bill would have given it.

THE SANITARY CODE.

WE understand that the present board of health of Greater New York has re-enacted with but little change the sanitary code enforced prior to its taking office, retaining the highly objectionable section No. 225, which makes it obligatory on physicians to report every case of pulmonary tuberculosis occurring in their practice. We should have thought that the sentiments of the profession, so frequently, freely, and forcibly expressed on this point, would have led the present commissioners of health to hesitate before enacting this unnecessary and offensive provision. It is to be regretted that the health board shows in this matter a disposition to ignore the wishes of the profession rather than a desire to conciliate it. Nothing helps any health board in its efforts to educate and protect the people more than the cordial indorsement of the medical profession.

TWO GREAT BRITISH SURGEONS.

MUCH has already been written concerning Harvey and Hunter, but, as the old saying that "you can't have too much of a good thing" is true, the two biographies recently published of the above-mentioned great men are welcome. The life of William Harvey has been written by D'Arcy Power, and that of John Hunter by Stephen Paget. Each of these books has been compiled with great care, and the information contained therein has been procured from reliable sources. It is fitting, too, in a high degree that the lives of these two men should be issued simultaneously, although their lives are a hundred years apart, as they were both pioneers in their particular branches of science. Harvey may be said to have founded modern medicine by his discovery of the circulation of blood, while Hunter with equal truth may be hailed as the father of modern pathology.

Harvey was born at Hastingleigh, in Kent, on April 1, 1578, and was educated at Kings' School, Canterbury, and Caius College, Cambridge. Thence he proceeded to Padua, which was probably at that time the most famous medical school in Europe. The celebrated Vesalius then held the professorship of anatomy there. In the year 1602 Harvey gained the degree of doctor of physic at Padua, after which he

returned to England and it is believed commenced to lecture on anatomy at St. Bartholomew's Hospital in 1616. In 1628 he published, at Frankfort-on-the-Main, his theory of the circulation of the blood. Harvey was physician to Charles I., and was treated by that ill-fated king with much consideration. However, as was to be expected, when the Parliamentarians obtained the upper hand, he suffered considerably for his loyalty. At the restoration he was knighted by Charles II., and died of gout at the ripe old age of eighty, at Roehampton, on June 3, 1657.

John Hunter was born in the vicinity of Glasgow in 1728. When a youth he absolutely refused to apply himself to book study, but preferred to spend his time watching and noting the habits of insects, birds, and animals. This neglect of books was responsible for Hunter's ignorance throughout his life of composition and spelling. In 1773 he delivered his first course of lectures on the "Principles of Surgery." As a lecturer Hunter was decidedly eccentric, although able to impart his knowledge to others. Among his pupils were Astley Cooper, Abernethy, Thomson, Cline, and Edward Jenner. Between Jenner and Hunter there was a great friendship, so much so that when a young man Jenner lived in Hunter's house and was instrumental in obtaining a large part of the 13,682 specimens which made up the latter's magnificent collection. In private life Hunter is described as averse to society, and many amusing tales are told of his brusqueness and absent-mindedness when, as happened on some occasions, he returned home to find his house filled with guests. His whole soul was in his work, and he grudged every moment that took him away from it. Hunter died of angina pectoris, from which he had suffered for many years, on October 16, 1793.

ANNUAL REPORT OF THE STATE BOARD OF CHARITIES.

The thirty-first annual report of the New York State board of charities has recently been issued. It appears that the board had a special interest in comparatively few of the measures of general legislation brought forward in 1897. The one in which it took the greatest interest was the "placing-out bill." This was an act giving to the "board" the power of drawing up rules and regulations in regard to the placing out of children. As, however, there was much opposition, the governor decided to withdraw his approval, and the measure failed to become law. The board holds that the present methods of placing out children are subject to much abuse, and expresses the hope that a statute regulating this matter will be passed shortly. Twelve of the State's charitable institutions were visited and inspected by the board, as well as nine under private management but mainly supported by State appropriations. The complaint is made that too much expense is incurred, as a rule, in the erection of buildings for charitable purposes. When the statement is made that as much as $1,000 *per capita* has recently been paid for housing, it cannot be denied that the complaint is just criticism. This is a matter that should be thoroughly looked into, for it is surely scandalous that the public money should be expended on the erection of palatial buildings, when it is plainly shown that half the amount would suffice to furnish well-equipped and substantial buildings, fully equal to all the requirements of their inmates. The inspection of the existing charitable institutions exhibited on the whole a satisfactory state of affairs, and demonstrated the fact that considerable progress has been made in their management.

AGAINST SPITTING.

An anti-expectoration crusade is now being conducted by the Woman's Health Protective Association. The health board of New York is said to have promised its full co-operation with the association, and to have expressed special sympathy with the movement against expectoration. It is stated that some of the street cars in New York are in such a disgraceful state from the prevalence of the spitting-habit that they are not fit for a human being to enter. The president of the Woman's Association suggested as a remedy for this condition of things that the conductors should be supplied with tickets bearing the words, "Do not expectorate on the floor—by order of the health board," to be handed to passengers who are seen breaking the law. It is thought that this will give comparatively little offence to the offender, and will thus prevent unpleasant scenes. On the other side of the ticket will be printed the words, "Keep this in your pocket," so that, after reading the wholesome advice, the sinner against the laws of decency shall not be guilty of breaking another ordinance against scattering papers on sidewalks and in cars. It is said that the association does not intend to rest from its labors in regard to the question of expectoration until it is settled in one way or the other, either by the enforcement or the repeal of the law. This action on the part of the Woman's Association is greatly to be commended, and is, further, one in which women are chiefly interested. What can be imagined more nasty, to say nothing of the insanitary bearings of the matter, than for a lady to be condemned to sit or walk in a street car whose floor is plentifully besmeared with unpleasant expectorations?

A Suspicious Scheme.—We learn from the *Dubuque Times* that a bill has been introduced into the Iowa State legislature to exempt from the examination required by the medical-practice law all graduates of the medical department of the Iowa State University. The reasons urged for the desired exception may be cogent ones (we have not seen them stated), but to the uninitiated it looks like an unworthy attempt to entrap medical students in this particular school and to draw their dollars into the pockets of the professors. At any rate we hope the physicians of the State will see to it that their lawmakers are enlightened as to the probable results of such unwarranted favoritism before they pass the act.

News of the Week.

A Case of Plagiarism. — Our attention has been called to an imposition recently practised upon us by the alleged author of an article on "Angina Pectoris," published in the MEDICAL RECORD of January 8th. We find on examination that the entire article, with the exception of a few words on treatment at the end, was lifted bodily, word for word, even to the punctuation and paragraphing, from the work on "Heart Disease," by Sir William Broadbent and John F. H. Broadbent, published by Baillière, Tindall & Cox, of London, in 1897. The only changes in the article published in these columns were omissions of credit given by the real authors to other investigators for original work done by them. We deeply regret having been the unsuspecting agent of such an outrage on Sir William Broadbent, although we trust that he will agree with us that we showed good taste and judgment in accepting such an excellent contribution. As for the alleged author of the article in the MEDICAL RECORD, we commend his case to the earnest consideration of the Saginaw County (Michigan) Medical Society, before which he claims to have read Sir W. H. Broadbent's scholarly description of angina pectoris.

Professor Hitzig, of Halle, has been mentioned as honorary member of the London Neurological Society, in the place of Du Bois-Reymond, deceased. The number of honorary members in this society is limited to six.—*Berlin. klin. Woch.*

Professors Senator and Ewald, of Berlin, have been unanimously elected as honorary members of the Moscow Therapeutic Society.—*Berlin. klin. Woch.*

Drs. Nathan E. Brill and Morris Manges were appointed visiting physicians to the Mt. Sinai Hospital, at a meeting of the board of directors, held February 13th.

Female Medical Practitioners in Germany.—It is stated in *The Hospital* that, although the German universities do not as yet grant medical degrees to women, the chancellor is about to open the state examination to them, and as this examination is the one portal to the legal practice of medicine in Germany, and has to be undergone even by members of the universities, the women's right to practise in that country will be fully secured.

An Operation on Sarah Bernhardt.—Dr. Samuel Pozzi, of Paris, operated on February 16th upon Mme. Sarah Bernhardt, the French actress, for the removal of an intraligamentary cyst. The operation, which was performed at Dr. Pozzi's private hospital, is reported to have been entirely successful.

Hospitals in Alaska.—A company has been formed to establish hospital stations along the route of travel to the Klondyke, similar to those in Northern Michigan. It is intended to organize a hospital service at Dyea, Lake Bennett, Stewart River, Dawson, Fort Cudahy, Circle City, Minock Creek, and Copper River. The first station to be organized will be at Dyea.

Dr. William H. Welch, of the Johns Hopkins University, Baltimore, has been appointed by the governor of Maryland a member of the State board of health, and has accepted the position.

Dr. Carl Johnson, of Denver, Col., has been appointed United States vice-consul at Amoy, China, marshal of the consular court there, and also United States port surgeon.

Recipe for a Tsarevitch.—Poor Dr. Schenk, of Vienna, who so rashly asserted his alleged discovery of the secret of sex determination, has already suffered more than can be compensated for by the royalties on his promised treatise. It is said his mail contains hundreds of letters from anxious women all over the globe, asking how they can bring about the conception of a male child. The gossips of Vienna will now have it that the Tsar of Russia, who is bothered with girls, has sent to the professor of sex to learn what diet the Tsarina should resort to in order to bring forth a male Romanoff. This report has apparently filled Professor Schenk's cup of bitterness, for he denies all knowledge of the Tsar's desires and declares that his life is being made a burden to him. His colleagues, he declares, are ridiculing him, and the public has tried to force him upon a career that is distasteful to him. He asserts that he has never undertaken the professional treatment of patients to determine the sex of their offspring, and he wishes the world to know that he never will do so.

Amendments to the Brush Bill.—Senator Brush, the father of the bill limiting the powers of the New York City board of health, has stated that some of the features which the members of the board claimed to regard as the most objectionable had been eliminated. The prohibition of the sale of vaccine virus and antitoxin would not now apply within the city. It was intended only to prevent their sale by the health board to the city of Chicago, the United States army, and other outsiders. The provisions to keep the police board president out of the health board and to exclude tuberculosis and other diseases from the list of contagious disease have been stricken out. All that the bill provides for now, Senator Brush says, is to permit a physician to be president of the board, to limit the jurisdiction of the department to matters of health specifically, to require that all vaccinators must be physicians, to fix a penalty for failures to report births, and to make the mandatory issue of warrants under the sanitary code contingent on the complaint of the board of health instead of any citizen. According to an Albany dispatch, the commissioners still object to the limitation of their antitoxin trade, and believe with England that the markets of the entire world should be open to all without restriction.

Mr. Gladstone's Malady.—It is reported in London that Mr. Gladstone is suffering from an affection of the nose, alleged by some to be necrosis of the nasal bones, by others malignant disease. It is this, it is said, which has been at the root of the obstinate neuralgia which has tried him for some months past.

The Tsarina is reported to be suffering from a mild attack of measles.

The Health Board and the Milk Business.—The following item is clipped from the *Commercial Advertiser* of January 25, 1898: "Health-board milk. President Straus adopts Mr. Straus' scheme. President Nathan Straus, of the health department, has taken up Nathan Straus' idea of dispensing sterilized milk to children. Mr. Straus had some trouble with the old health board about this very subject. But he succeeded the old board with his board, and he has been studying the old board's records and statistics of the death rate of children. His conclusion is that he was right all along. Parents should be compelled to give their children proper food, and sterilized-milk stations will be established all over town. 'The great death rate among children is undoubtedly due to carelessness on the part of parents in giving their children improper food,' said Mr. Straus. 'I believe that if proper care is taken and the children are given proper food in summer the death rate will be decreased till it reaches the average death rate for adults, which last week was 17.95 per 1,000. In 1893 there were 83,148 under two years of age, of which 14,427 died, the death rate being 173.5 per 1,000. In 1894 there were 85,582, of which 14,118 died, the death rate being 165 per 1,000. In 1895 there were 87,886 children under two years of age, and 14,087 died, a death rate of 160.3 per 1,000. In 1896, out of 91,482 children, 13,888 died, making a death rate of 151.8 per 1,000. Last year (1897) there were 94,154 children under two years of age; of these, 12,897 died, bringing the death rate down to 137 per 1,000. I attribute this decrease in the death rate mainly to the increased use of sterilized milk. These stations will probably be under the charge of the health department.'"

The Therapeutics of Music.—Mr. Gladstone, it is said, has found music a great relief during his sufferings of the last few weeks. Miss Geraldine Liddell, the performer who charms his neuralgia, is an exquisite musician, and her melodies have a peculiarly soothing effect.

Professor von Esmarch has announced his intention to resign the chair of surgery at the University of Kiel at the end of the present semester. His reason for retiring is advanced age, he being now over seventy-five years old. He was appointed professor of surgery at Kiel in 1857. He is also a surgeon-general in the German army.

The Plague in Bombay.—A fire destroyed one of the temporary plague hospitals at Bombay on February 19th. There were ninety-nine patients in the hospital at the time, twelve of whom were Europeans. All were saved from the flames, but three died as a result of the moving. Several of the nurses and one physician sent from England to care for the sick have themselves been taken down with the plague.

Social versus Professional Visits.—A young physician, practising in a city in Ulster County in this State, recently brought suit against a former patient, a young lady, from whom he was unable to collect a bill of $60 for professional services. The defendant's attorney contested the bill, which he characterized as exorbitant. He said that many of the alleged professional calls were of a social nature. The plaintiff would call at times when he wasn't expected, and keep the defendant and her sister from their household duties. In view of the annoyance and loss of time the young lady alleges that she suffered through these visits, she puts in a counter claim of $100. The case will be tried before a jury next month.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the two weeks ending February 19, 1898. February 11th.—Passed Assistant Surgeon L. H. Stone, retired, February 10th. February 12th.—Assistant Surgeon G. C. Hubbard sent to St. Elizabeth's Government Hospital for the Insane; Assistant Surgeon J. C. Thompson detached from the naval hospital, Mare Island, Cal., and ordered at once to the *Mohican*.

International Congress of Hydrology and Climatology.—The fifth triennial session of this congress will be held at Liége, Belgium, September 25 to October 1, 1898. There will be, in addition to the general sessions of opening and closing of the congress, daily sessions of each of the three sections of medical hydrology, medical geology, and climatology. The permissible languages are French, German, English, and Flemish. The registration fee is 20 francs ($4) for members of the congress and 10 francs ($2) for their wives. Those intending to read papers should send the title and conclusions of the same to the secretary at least one month before the opening of the congress. The president of the committee of organization is Dr. G. Dewalque, the secretary-general Dr. G. Jorissenne, and the treasurer Dr. J. Delaite, all of Liége.

The Streets of New York are becoming visibly dirtier than they were before our recent change of rulers. We earnestly hope, for the sake of the new street-cleaning commissioner's reputation and peace of mind, that this deterioration will not be progressive. If it is, somebody will be responsible for the deaths of many helpless children next summer.

Addition to Edinburgh University.—The infirmary at Edinburgh and the university buildings devoted to medicine have long been among the greatest prides of the grand old city. Through the munificence of a private citizen the university has recently received a magnificent addition. Mr. McEwan, M.P., at his own cost, has caused to be erected a hall, bearing his name, for the use of the faculty and students of the university. This building, on which has been expended a sum approaching $1,000,000, was opened on December 3d by Mr. A. T. Balfour, M.P., the chancellor of the university. Mr. Balfour, in his reply of thanks to Mr. McEwan for his gift, made in the course of his speech some remarks which should gratify the *amour propre* of the American nation. These were as follows: "I have seen with regret, sometimes almost amounting to shame, the

extreme difficulty which there has been, not merely in Edinburgh, but in connection with other great seats of learning, in obtaining from the liberality of a not illiberal public sufficient means to make our great universities all that British universities should be. In this respect we could ill bear comparison with our cousins in the United States. I believe that the educational value of a worthy setting of a great university is not to be despised."

Dispensary Abuse in New York City and State.—Statistics collected by the State board of charities show the following as the work of the free dispensaries in the seven largest cities of the State for the year 1897:

	Number of Patients.	Per Cent. of Population.	Number of Prescriptions.
New York	1,077,149	71	1,699,468
Brooklyn.....	252,695	31.3	455,940
Buffalo	14,886	5.5	32,509
Rochester.....	2,476	1.5	6,695
Albany	20,345	21.4	17,939
Syracuse.....	8,796	9.9	6,116
Troy	715	1.2	716

Besides the medical relief furnished by dispensaries, various charitable societies in the city of New York provide medical attendance for the poor at their homes. The secretary of the board states that the statistics for New York City, or that part of the present city included in the boroughs of Manhattan and the Bronx, do not represent all of the institutions, as only sixty-eight of the ninety-seven reported to the State board. He says that he has investigated many cases of applicants for free treatment at the dispensaries, and in fully half of them found that the people were perfectly able to pay for the services of a physician and should have been compelled to do so. It is a common thing to find families whose salaries range from $20 to $40 a week going to dispensaries for treatment, and, in one instance, a storekeeper and real-estate owner worth over $100,000 was one of the applicants under investigation.

Vivisection.—A new crusade against vivisection, says the *International Medical Magazine*, has been started recently in Baltimore. It is headed by Cardinal Gibbons, Bishop Paret, and other prominent citizens of Baltimore. An antivivisection society has been formed, and the medical school of Johns Hopkins University has been selected to suffer from its attacks. Such periodical outbreaks are, in the end, says the New York *Medical Journal*, of great value to science, for the study of mental epidemics.

The Texas Tax on Physicians.—The members of the Western Texas Medical Association, at a meeting held January 27th, adopted resolutions denouncing the "occupation tax" imposed upon medical practitioners in the State by the last legislature and urging the repeal of the act authorizing this imposition. An effort will be made to secure pledges from candidates for election to the next legislature that they will do everything in their power "to enact laws the purpose of which shall be to elevate the standing of medical education, regulate the practice of medicine, and to consign to eternal oblivion the act imposing an occupation tax on the profession."

Practice of Medicine in Hawaii.—A license is now required in order to practise medicine or surgery in the Hawaiian Islands, such license to be granted only upon the written recommendation of the board of health. The licenses of those who, at the time of the passing of the act enforcing the foregoing regulation, were already in practice will remain valid, subject to the provisions of this act. The board of health is prohibited from recommending any person for a license, except the said person has been duly examined and found to be possessed of the necessary qualifications.

Deportation of Insane Patients.—During the past fiscal year the State commission in lunacy sent to other States and deported to foreign countries one hundred and ten alien and non-resident insane inmates of State hospitals who were not properly charges of New York State.

Obituary Notes.—Dr. James Wilkinson, of Jersey City, died at his home in that place on February 17th. He was born in England in 1837, but came to this country with his parents at an early age. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1858.—Dr. Conant Sawyer died at his home in Auburn, N. Y., on February 21st, of pneumonia. He was physician to Auburn Prison, to which place he was appointed about ten years ago.—Dr. Sumner Laughton, of Bangor, Me., died at his home in that city on February 8th, at the age of eighty-six years. He was graduated in medicine from Bowdoin College in 1834. He had practised in Bangor since the autumn of 1849. He was a member of the consulting staff of the Eastern Maine General Hospital.

Obituary.

EDWARD CONSTANT SEGUIN, M.D.,

NEW YORK.

Dr. E. C. Seguin, at one time one of the best known of American neurologists, died at his home in this city, on February 19th, of a chronic affection of the liver. Dr. Seguin was born in Paris fifty-five years ago, but was brought to this country by his father, Dr. E. O. Seguin, when he was seven years old. He was a brilliant student, and was graduated from the College of Physicians and Surgeons in this city, at the early age of twenty-one years, after having already served two years as medical cadet in the regular army. After the war he was stationed as post surgeon at different forts in New Mexico, where he was ordered at his own request in the hope of relief from a beginning lung trouble. He remained there a few years, recovering his health perfectly. Afterward he resigned from the army and went to Paris to study in the clinics of Charcot and other neurologists. He returned to this country in 1870 or 1871, and at once began the practice of medicine in New York City, where his great abilities won for him immediate fame and position. For nearly fifteen years he was a member of the faculty of the College of Physicians and Surgeons, and was also actively engaged in neurological practice and in editorial and other literary work. His health had been poor for some time before his death and he had lived in practical retirement for several years. He was an honorary member of many neurological societies in Europe.

Clinical Department.

ABDOMINAL ABSCESS CONTAINING ONE AND ONE-HALF GALLONS OF PUS; LAPAROTOMY; RECOVERY.

By W. H. IRVINE, M.D.,

MEMBER OF THE BRITISH MEDICAL ASSOCIATION, OF THE AMERICAN MEDICAL ASSOCIATION, ETC., BOIESTOWN, NORTHUMBERLAND CO., N. B.

The case under consideration presents a history rather unique. The patient, J. Mc——, aged thirty-six, received about twenty years ago an injury in the left lumbar region, caused by several logs passing over his body, he having fallen from a "brow" (*i.e.*, a pile of logs placed on the side of a stream during the winter season, and rolled into the stream in the spring). A detailed history of the patient's suffering is wanting. He, however, was confined to his home for several months; yet the only inconvenience from which he suffered was a lameness in the right hip, which would at times almost disappear, yet has been present more or less since the time of the injury twenty years ago.

Present history: I saw the patient on May 20, 1897, when he was complaining of intense pain over the region of the left great trochanter. The temperature was 103° F. and a fraction. He complained of "cold chills" followed by "hot flashes" for several days. He had been feeling poorly since the 2d day of May, when he strained his side in an effort to lift a log with a peevy, while working on the river. He tried to "work the sickness off;" walked forty miles into the woods, got worse, and walked back and about six miles farther to see the doctor, making in all a walk of over eighty miles.

When seen he was lying flat on his back, with the legs in complete extension. He said he felt "first rate," all save his left hip, which was very sensitive to pressure. Inspection revealed nothing abnormal in the region of the hip, however. A fulness, occupying the left iliac region and extending upward and to the right of the linea alba, was plainly to be made out, being dull on percussion—the dulness blending with that of the spleen on the left, and extending to the ensiform cartilage above and to the right one inch or more beyond the median line. There was no discoloration of the skin. The bowels had moved regularly and the patient had not vomited; the urine did not contain pus or albumin. Aspiration revealed thick, dark, very offensive pus. Chloroform was administered and laparotomy performed, the patient lying on a lounge in a little, old, one-story country house. Antiseptic measures were as strictly enforced as was possible under existing circumstances.

An incision was made parallel with the fibres of the external oblique, the upper limit being about on a level with the anterior superior iliac spine, and about three inches long. The abscess wall was found adherent to the abdominal walls; it was incised, and pus of the most obnoxious odor welled forth, sufficient being caught to fill a one-and-one-half gallon vessel. One would hardly believe that such a quantity of material could be held in an abdominal cavity.

The patient stood the operation well, but the character of the breathing became somewhat alarming, presumably from sudden removal of pressure from the diaphragm, and one-twentieth grain of strychnine nitrate was administered hypodermically; the cavity was irrigated with bichloride, 1 to 3,000, subsequently with sterilized water, and a drainage tube of ½ calibre inserted. The cavity was daily irrigated with sterilized water. Convalescence was uninterrupted. The abscess wall contracted daily, so that in one month's time it felt like a scirrhus growth adherent to the pelvic wall. When last examined, about two months ago, it was apparently absorbed. The patient has never had a pain in the hip since, is apparently a perfectly well man, and says he never felt so well before.

The points of interest in this case are: (1) the obscurity of the source of the pus; (2) the absence of pain, save in the hip; (3) the absence of all subjective symptoms, except as stated; (4) the tolerance of such a quantity of fluid in the abdomen; and (5) the disappearance of pain from the hip.

I am inclined to think that the following may be excluded as causes: (1) Perinephritic abscess; (2) lumbar abscess; and (3) necrosis of bone; and that either the pelvic cellular tissue, or perhaps the hip itself, played the all-important rôle in the original production of the contents of the abscess.

MATERNAL IMPRESSIONS.

By A. C. FLACK, M.D.,

FREDONIA, KAN.

I WISH to add to the literature of the above subject by recording the following case that occurred in my practice: August 7, 1894, I was hastily called to see a child that had been bitten by a rat, soon after she had been put to bed. On arriving I found the child in her mother's arms. The rat had bitten her on the external surface of the foot near the little toe, and a few drops of blood had escaped and trickled down the side of the foot. On November 13th—ninety-eight days from the above date—this mother gave birth to a child marked by a red blotch on the foot, in a position exactly corresponding to the blood stain on the child bitten by the rat.

SOME INTERESTING EYE CASES.

By J. H. McCASSY, M.A., M.D.,

DAYTON, OHIO.

CASE I.—Irido-dialysis, or detachment of the iris from the ciliary body. S——, aged thirteen years, while playing at school last April, was accidentally struck with a stone, of the size of a pigeon's egg, on the upper part of the left eyeball. His vision became blurred immediately, so that he could not count fingers. He was brought to my office at once. I found a rent in the iris, about three-eighths of an inch long, at the junction of the iris with the ciliary body. Free hemorrhage into the chambers of the eye had taken place, which obstructed a view of the fundus.

Atropine solution was used once daily. Saturated boric-acid solution was used several times daily and five grains of iodide of potassium was administered four times daily.

The blood in the anterior and posterior chambers of the eye was speedily absorbed and normal vision returned in one week. Treatment was discontinued at the end of two weeks and the boy returned to school. The tear in the iris never closed and the pupil remained oval on the upper side.

CASE II.—Diplopia due to injury of the right orbit. In May last, L——, aged fourteen years, while trying to explode a cartridge, was struck in the right orbit by the bullet, producing considerable laceration of the part beneath the supra-orbital ridge. A large induration followed with crossed diplopia.

Eight to ten grains of iodide of potassium was administered thrice daily. The induration was painted twice daily with tincture of iodine. After this line of treatment had been used for eight weeks, the induration disappeared and good binocular vision returned.

It would seem that hemorrhage into the orbit was the cause of the diplopia: a septic process would have caused either abscess or orbital cellulitis. The speedy

absorption speaks in favor of hemorrhage. The diplopia was the result of the mechanical impediment and perhaps of direct injury to the muscles.

Case III.—Secondary hemorrhage following iridectomy. M. M——, aged fourteen years, had a dense central leucoma on the cornea of the right eye, caused five years previously by ulcerative keratitis, induced by too long and too frequent bathing in the river. This virtually blinded the eye for binocular vision. The cornea was clear in the outer segment. I made a small iridectomy outward and normal binocular vision was restored. The boy was confined to bed only two days. On the evening of the third day he felt so well that he took his own counsel and slipped away and viewed a bicycle parade until 10 P.M. This caused profuse hemorrhage into the chambers of the eye, blurring vision completely and rendering an ophthalmoscopic view of the fundus an impossibility.

He was given one grain of calomel as a cathartic; five grains of iodide of potassium was given four times daily. The eye cleared up in a few days. Vision, $\frac{20}{20}$. Using the eye too soon was undoubtedly the cause of the hemorrhage in this case.

Case IV.—Refraction changed from E to M. Mr. B——, aged forty-seven years, a travelling salesman, got a hot cinder in his right eye in August, 1897, while riding on the train. Redness of the sclera, lacrymation, and pain followed. He consulted a general practitioner in Kentucky, who advised him to use a quack eye water, which he did, but the pain in the eye and brow became so severe that he was compelled to abandon travelling and return to his home in Dayton, Ohio.

Examination, September 2d last, showed the case to be one of severe plastic iritis with extensive posterior synechiæ. A one-per-cent. solution of atropine was pushed for ten days, when the adhesions yielded fairly well. His temple was leeched several times and hot applications were diligently and judiciously used. Recovery took place in about eight weeks, but the refraction had changed. The best distant vision was secured by the aid of a -3.25 spherical lens, and near reading was best without any lens. In August, 1896, I examined this eye and found D. V. $\frac{20}{20}$, and it was not improved by the addition of any kind of lens. At that time he accepted a $+2.50$ sphere for reading.

The change of refraction may be caused by three things: (1) Elongation of the eyeball by a softening of the sclera and ectasia. (2) An increase of the refraction of the lens by its getting thicker. (3) During an iritis or irido-cyclitis or irido-choroiditis the anterior chamber may become shallow and the lens advance; by this the nodal point of the eye advances and the state of refraction becomes increased, *i.e.*, myopic. This is always a much-to-be-feared phenomenon and a bad sign. I do not know which of the three possible causes to assign in this case. If it is due to the lens becoming thicker, I would therefore be on the lookout for the possible formation of a cataract in this lens after a while. Change of refraction is not very frequent.

Case V.—Congenital displacement and deformity of the pupil. Mr. S——, aged sixty years, retired from the pulpit four years ago on account of catarrhal deafness and impairment of his voice. The pupil of his left eye, although about normal in size, is balloon or egg shaped, with the large end situated close to the limbus and the small end extending toward the ceatre of the cornea. The space that should be occupied by the pupil is covered by a blue iris. The eye is amblyopic, not possessing more than one-third normal vision. Both eyes are slightly myopic. The right eye is good, having been his mainstay during his busy and studious life in the ministry.

116 South Ludlow Street.

PURPURA SYPHILITICA.

By CONRAD P. KORNREICH, M.D.,

ATTENDING PHYSICIAN, INTERNAL DEPARTMENT, EAST SIDE DISPENSARY, NEW YORK.

That this disease of the vascular system often owes its origin to a syphilitic poison existing somewhere in the body, as in the blood itself or in the vessel walls, seems to me to be an apparent and undoubted fact, as is shown by the following interesting case which came under my observation some time ago.

C. S——, male, unmarried, aged twenty-five years, by occupation a bookkeeper, consulted me about "a bloody rash," as he termed it, which on examination was found to be irregularly distributed over the body, on arms, chest, back, abdomen, thighs, and legs, causing him considerable anxiety. The nature of the lesion was as follows: flat, not elevated above the surface of the skin, irregular and diversified in form, and of a dark purplish hue, which discoloration became lighter, but did not entirely disappear on pressure.

The patient seemed otherwise to be in fair physical condition, except for occasional severe attacks of headache, which he said occurred chiefly at night. His appetite was good, there was no loss of flesh or strength, and altogether his other bodily functions were in comparatively good order. Further inquiry enabled me to elicit a distinct syphilitic history, the initial lesion having manifested itself eighteen months ago, there still being present some distinct symptoms of this disease, such as alopecia capitis, nocturnal headache, irregular pains in the body; no rheumatic history was elicited. On inquiry as to the mode of treatment and the length of time he had been under treatment before consulting me, I learned that he had received mercurial inunctions as well as internal medication, both of which he was in the habit of neglecting at various periods during his course of treatment. This fact convinced me of the correctness of my diagnosis of tertiary syphilis, and that this purpura was of syphilitic origin.

We know of the many causes which have been assigned to account for the occurrence of purpura; we know that it may occur at any period of life, and in both sexes, and in the most varying conditions of health, as a symptom in different diseases and cachexiæ, after the ingestion of certain drugs, and under other circumstances too numerous to catalogue here. We also know, and have seen, what effect syphilis has upon the general economy, its deteriorating effect on the bones, muscles, and the various organs, and the numerous bodily functions. Its effect in this instance was upon the vascular system: 1, a change in the blood itself which allows of its passing through the walls of the vessels; 2, a change in the vessel walls themselves which permits the blood to pass through them.

Some authorities believe that purpura is of microbial and infectious origin. Letzerich wrote on this subject in 1889, and described the "bacillus purpuræ hæmorrhagicæ" as the cause of the disease.

When first this patient came under my treatment I treated the purpura as is generally recommended and practised, that is, by putting the patient in good hygienic surroundings by administering iron and ergot, turpentine, dilute sulphuric acid, nitrate of silver in pill form, one-eighth to one-sixth of a grain three times daily, and other astringents. Hydrotherapy in its various forms was carefully and persistently followed up. These various measures were strictly adhered to for fully three weeks, and instead of improving the patient seemed to be getting steadily worse. The headache still continued with increasing severity, the appetite was failing, there was beginning loss of flesh and strength, and altogether the patient was in

abject misery. I had by this time become discouraged with my form of treatment, and as an experiment put my patient on an antisyphilitic treatment—that is, the regular mixed treatment. Beginning with iodide of potassium, ten grains three times a day, I gradually increased the dose to thirty grains three times daily, with increasing doses of from one-fiftieth to one-thirtieth of a grain of bichloride of mercury in one week, and to my great surprise the blotches began to fade away by the second week after I had put him on the mixed treatment; by the third week the headache had entirely disappeared, and by the fourth week there was no sign of purpura to be seen on the body.

REPORT OF TWO CASES OF COLITIS OF CURIOUS ORIGIN.

By WILLIAM J. GREANELLÉ, M.D.,

NEW YORK.

While in attendance on an elderly gentleman suffering from endocarditis, I was asked at one of my visits to see his daughter-in-law, who had been seized with "an upset stomach" while visiting him during his illness. The young woman was of petite build but had evidently enjoyed good general health. She stated that she had been taken with vomiting and diarrhœa the day before, and as her illness did not yield to home remedies she thought it best to see a physician. Apart from the diarrhœa she felt quite well. Careful questioning elicited no evidence of error in diet, nor could any satisfactory cause of her condition be discovered.

On examination there was found a broad, coated tongue, moist; slight tenderness over the abdomen; and a rectal temperature of 97° F. She was instructed to keep her bed, and small doses of castor oil were ordered every three hours, in emulsion. The diet was restricted to beef tea and scraped beef, there having been no vomiting after the onset of her illness.

The next morning her symptoms had not improved; the stools were as frequent as they had been from the start (one every two hours) and were of the same consistence—the only noticeable change was the beginning of slight pallor. I was, however, informed that her husband was now also ill with the same symptoms, and such I found to be the case on examination. The cases were so nearly identical that I need follow but one in detail clinically, adding but this one modification—that in the case of the husband the symptoms were not quite so severe, the loss of flesh not so great, and the ultimate recovery a little more rapid.

Renewed investigation and careful cross-questioning still failed to explain the origin of the trouble. The treatment was continued with the addition of twenty grains of bismuth subnitrate every four hours and of five minims of deodorized tincture of opium to each dose of emulsion of oil.

On the evening of this day Mrs. T—— complained of nausea and the castor oil was discontinued, the bismuth being increased to thirty grains every three hours; the frequency of the stools remained the same. The temperature remained at 97° or 97.4° F., and there were well-marked pallor and beginning emaciation; the pulse ran from 90 to 100 until convalescence.

On the third day of treatment I found that the stools had become much more frequent, the nausea continued, and there was tenderness fairly well marked over the line of the colon. The stools had changed in appearance from simple diarrhœal stools to stools of rather a dysenteric character. No explanation could be found by the most minute investigation of both cases. The treatment was continued. The evening of the third day Mrs. T—— complained that since my visit in the morning she had been seized with uncontrollable vomiting whenever she tried to take the bismuth. She stated that she had no objection to the medicine and did not mind taking it; but in spite of her best efforts she vomited as soon as the bismuth was in her mouth. The stools were now quite dysenteric in character, being full of mucus and occasionally blood streaked; defecations occurred every half-hour, and with some tenesmus. The vomitus consisted of mucus, bile, and water. The cases puzzled me: they looked exactly like cases of arsenical or bichloride poisoning, so much so that I remarked to a fellow-physician that I felt sure that there was some mineral poison at the bottom of it all, and, recalling the occasional contamination of bismuth by arsenic, I went to the druggist who had answered my prescription and asked him if he had tested his bismuth. He was one of the most reliable druggists in upper New York, and he assured me that he tested every pound of bismuth that came into his store, and offered to let me test the stock bottle from which my prescriptions had been filled. I explained the reason for my inquiry, and stated that I had discontinued the bismuth because I had feared it was contaminated, it being quite evident that the patients were made worse by the drug, usually so inert. The frequency of stools and the now increased tenesmus were controlled by deodorized tincture of opium and belladonna suppositories, all other medication being discontinued, while brandy had meanwhile been added as food and stimulant. The cases resembled nothing so much as they did the cases of "bichloride colitis," seen once in a while in a surgical ward.

On what was the fourth day of treatment I learned that both Mr. T—— and his wife had been taking a much-advertised skin medicine for some three months prior to their illness. I had previously asked if any tonics or other medicines had been taken, but had always been told "No" through forgetfulness, and it was only by a mere chance that Mrs. T—— finally remembered the patent medicine which she had been using. Neither patient was syphilitic, and they had taken the remedy only "as a good tonic." I was in entire ignorance of the nature of this remedy, beyond what was claimed in the advertisements. I was, however, strongly suspicious of that "tonic." I at once questioned a druggist of my acquaintance and he stated that there was about one-thirty-second of a grain of bichloride of mercury in each half-ounce of the "mixture." I put both patients on small doses of Rochelle salts at once; both improved promptly and made steady recoveries. The wife had become more emaciated, and had had a somewhat more severe attack than had her husband, and her convalescence was correspondingly slow. At the end of three weeks from the onset of the trouble, both patients were following their usual pursuits, with, however, a strong aversion for all advertised "tonics."

The history of these cases points out the necessity of going most carefully into any and all possible (or impossible, I might almost say) causes for a given condition, and that such investigation cannot be too often repeated. It points out the danger in self-medication on the part of patients, and the latent harm that may lurk even in a well-advertised "tonic." A careful druggist may also at times be needlessly and unjustly blamed from misleading circumstantial evidence coupled with intentional or unintentional deception on the part of a patient: while a good and well-recognized method of treatment may receive severe criticism when subjected to an unexpected chemical struggle with "tonics" in the system of a patient. The evident irritation set up by the bismuth taken into an economy already charged with mercury is but too plainly set forth in the above history, by the vomiting and the aggravation of symptoms which it caused.

University Heights, New York.

HYSTERICAL APHONIA.

By JOHN WINSLOW, M.D.,

ITHACA, N. Y.

THE case of hysterical aphonia reported by Dr. Follett, in the MEDICAL RECORD of November 13th, recalls one of my own. A young woman had called a few times, at intervals of several months, for sudden attacks of complete aphonia, which had been promptly and entirely relieved by faradization of the crico-thyroids. The cure was so prompt and persistent as to suggest hysteria; so on the next occasion I placed in the circuit a rheotome controlled by the foot. Applying a strong current, as by accident, to indifferent regions of the neck, I shut it off before bringing the electrodes to the larynx. But the buzzing of the battery continued, and relief was again immediate and complete when the crico-thyroids were covered and the patient was told to speak.

152 EAST SENECA STREET.

SUPERNUMERARY TOOTH IN THE PALATINE VAULT.

By R. CADWALLADER, M.D.,

FALL RIVER MILLS, CAL.

A YOUNG man (Indian) came to me October 26, 1895, to have a tooth pulled. I ran over his mouth without finding a faulty tooth in his head; every one was perfect and sound. He called my attention then to its location. I found a tooth exactly in the median line of the palate on a transverse line between the two first molars.

There was no photographer within forty miles, or I should have had the vault reproduced with the tooth *in situ*. I extracted it with some difficulty. It measured one-half inch in length with a hooked root which penetrated the vault.

The recent work on "Anomalies and Curiosities of Medicine" contains a short note concerning supernumerary teeth in this situation, and states that Fanton-Touvet gives an example of a supernumerary tooth implanted in the palatine arch.

It would be useless to theorize as to how it came there. It could be developed only from a dental centre displaced, or else be a deciduous tooth forcibly implanted by some accident. Against this latter are its anomalous shape and the statement of the young man that it had been there ever since he could remember.

A CASE OF PUERPERAL SEPTICÆMIA UNSUCCESSFULLY TREATED BY ANTISTREPTOCOCCUS SERUM.

By HUBERT WORK, M.D.,

PUEBLO, COL.

MRS. W——, aged twenty-five, multipara, in perfect health, of good physique and family history, was taken with "flooding," September 9th, and expelled a fœtus, which from the description I supposed to be of about the fourth month.

September 18th, she expelled a placenta, which was promptly destroyed. I was called and found the patient's condition apparently good in every way. I made no examination, and was told that daily reports would be made to me, in order to save expense of visits.

September 27th, I was summoned, as her husband thought she "was having a little fever for some days past." I found the patient with a temperature of 105 F.; pulse, 120: and the other typical symptoms of puerperal infection. I ordered a large dose of quinine and small doses of calomel.

On September 28th I curetted the uterus and removed fragments of placenta. The temperature fell to 104 F.; pulse, 120. The quinine was continued in twenty-grain doses.

September 29th, the temperature was 105.5 F.; pulse, 130. I curetted again, but found no débris. The patient now had a severe chill, and the temperature soon rose to 105 F. and the pulse to 120.

By October 1st I was able to reduce the temperature to 102.5 or 103 F., and keep it down by constant applications of cold, meanwhile urging food and using stimulants.

On October 2d I injected ten cubic centimetres of antistreptococcus serum in the evening, the patient's temperature being 102.5 F.; pulse, 130.

October 3d, A.M., temperature, 104 F.; pulse, 128; P.M., temperature, 104.5 F.; pulse, 135. Violent diarrhœa, with retention of urine.

On October 4th I injected twenty cubic centimetres of antistreptococcus serum, with no apparent effect on the temperature.

On October 5th the temperature reached 106 F., and the pulse was exceedingly rapid and feeble.

On October 6th the patient died from puerperal infection.

I do not care to comment upon this history, except to say with Dr. Siff, who reported a case of puerperal infection in your issue of November 13th, treated by the antistreptococcus serum, "that it requires more than one test to convince a physician of the efficacy of a therapeutic agent."

THE CLINICAL REPORT OF FOUR CASES OF LAVAGE OF THE STOMACH BY THE AID OF KNAPP'S DIRECTOR.

By MARK I. KNAPP, M.D.,

NEW YORK.

ON August 29, 1896, appeared in the MEDICAL RECORD the description of my "stomach-tube director." It was then largely a new device and only theoretically correct. Since then, however, I have had occasion to use my director in four cases in which the introduction of the tube into the patient's stomach without the director proved an impossibility. Following are the cases:

CASE I.—Mrs. F. W——, forty-two years old, widow, had suffered from chronic gastric catarrh for over three years, during which time she had consulted many physicians. This malady made her very despondent and melancholy. Her friend who recommended me to her had succeeded in bringing her to me only after long and persistent persuasion. After an unsuccessful trial with medicines I advised lavage. My attempts with the tube in the ordinary way were fruitless. Neither persuasion nor coaxing availed anything. I then had recourse to my director, and the result was astonishing. It took me but a few seconds, and the tube was down in the stomach.

CASE II.—Mrs. L——, thirty years old, married, highly nervous, came to have her stomach washed, which I advised her some time before. I did not dare introduce the stomach tube without the director, and before the patient had realized anything the tube was in the stomach.

CASE III.—Mrs. C. S——, thirty-eight years old, married, had an operation for the removal of gall stones in January, 1896. In May she went to Carlsbad, and after she came back family affairs began to depress her spirits, and the diagnosis made subsequently by an eminent specialist was incipient melancholia. Her digestion was in a terrible condition. Lavage of the stomach was my advice, but for a long while I could not induce the patient to submit to it.

Attempts without the director proving valueless, I used the director, when I at once succeeded.

Case IV.—Miss F. S——, twenty-two years of age, attempted suicide on November 7, 1897. As is usual in such cases, the patient violently objected to the introduction of the tube. I then tied her arms behind her back, forced the mouth open with the handle of a spoon, and introduced the tube by means of the director into the stomach. Here my full expectations were realized. The patient struggled and bit, with the desired result of having the director kept in place and in apposition still better. In this case the director acted not only as such, but also as tongue depressor and mouth gag.

Now a few words in repetition as to the utility of the director. First, the physician need not introduce his finger into the mouth of the patient, thus avoiding possible danger to himself: second, the physician need not fear to go anywhere else than in the desired direction by simply pushing the director as far back as he can: and third, the patient is entirely at the mercy of the physician.

A few gentlemen contend, in derogation of the instrument, that we might introduce the tube through the nose. Well, at the very best, we can use only a small catheter: and secondly, is not one sometimes nonplussed in finding deviations there or hypertrophies?

230 Broome Street.

FORWARD DISLOCATION OF BOTH BONES OF THE FOREARM.

By F. A. AUGUR, M.D.,

NEWBURG, N. Y.

Owing to infrequency of occurrence, it may be of interest to mention a case paralleling the one of dislocation of the forearm, reported by Dr. Fulton in the Medical Record of November 20th. A boy, about ten or twelve years of age, fell from an apple tree that he was climbing, instinctively grasping a limb with his left hand, the falling weight of the body being thereby sustained by the left arm. This resulted in a forward dislocation of both bones of the forearm. Reduction in this case was performed with considerable difficulty, and necessitated the free use of an anæsthetic.

HYDRO-THERAPEUTIC PRINCIPLES IN THE TREATMENT OF TYPHOID FEVER.

By ELMER LEE, A.M., M.D., Ph.B.,

NEW YORK.

First, the internal administration of soft water, in definite doses, of proper temperature and at regular intervals (with a suitable placebo if necessary), according to the age and sex of the patient, the temperature of the fever, and the character of the urine, against which there are no veritable contraindications. The rule is to give an amount of water which would be equivalent to nearly one-fifteenth of the weight of the patient.

Second, the application of water of suitable temperature to the surface of the body, preferably in the form of sprinkle or rain contact with friction, at frequent and regular intervals, as indicated by the severity of the symptoms and the age and sex of the patient. The cold bath of Brandt may be useful, but is not imperative; in fact, satisfactory and rapid recovery may be secured without bathing.

Third, the application of compresses of linen, wrung dry from ice water, to the abdomen and to the head and neck, applied as often as necessary and as long as the fever continues.

Fourth, the use of warm, cool, or cold irrigations of the colon, with plain, soapy, or normal salt water, from one to four times a day, and from one to three litres in quantity, during the acute stage and while there is fever.

Fifth, assuming that there is an absence of hydrochloric acid and peptones in the gastric juice during the febrile stage in typhoid fever, food of every character and of any quantity is contraindicated, and can only augment the complications and prolong the disease.

Sixth, in collapse and exhaustion from hemorrhage, intravenous transfusion of one-half to one litre of decinormal salt solution is indicated and strongly recommended. The transfusion or subcutaneous injection is to be repeated from time to time till the crisis is passed.

Seventh, drugs and stimulants are absolutely contraindicated, as they are not essential to nutrition, and can but further increase the labor of the system and diminish its vitality in the process of oxidation and elimination of tissue waste and toxic products.

Eighth, in the hydriatic management of typhoid fever ulceration and perforation of the intestines have never been known to take place: also there are no distressing after-effects, as there are no baneful sequelæ.

Ninth, it is my experience and belief that when cases are seen within the first five days, typhoid fever can be aborted and convalescence established within ten days to two weeks, based upon intelligent application of hydrotherapy.

Tenth, a treatment which is so simple and always available, and which has been proven by experience with many thousands of cases, ought to secure its adoption by the profession.

MENSTRUATION THE CAUSE OF ACUTE OTITIS.

By F. PIERCE HOOVER, M.D.,

LECTURER IN OTOLOGY, NEW YORK POLYCLINIC; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL.

February 4, 1897, Mr. J. B—— brought his wife to see me, regarding her ears. He informed me that every few weeks she would experience excruciating pain, which lasted several days; more in the right ear than in the left. During the time the right ear would discharge something similar to matter.

Mrs. B—— was a healthy-looking young woman, brunette, aged twenty-two years; weight, one hundred and twenty pounds; of medium height; married one year. Previous to that time she had never experienced trouble with her ears, but regularly each time her menses came on since her marriage she suffered agony with them. She desired to know what should be done to alleviate her great discomfort. She said she never had had womb trouble; her family physician, who had attended her from childhood, had pronounced her in perfect condition. On being informed she would be unwell the following week, I requested her to call to see me immediately she felt any unpleasant sensation in her ears.

The morning of the 8th she called again, begging me to ease her pain: it was similar to the passing of a knife through her head from one side to the other. Looking in the ears, I found the drum membranes somewhat reddened, the left one more than the right, and in its lower inferior quadrant I noticed a puffed-out area. I at once decided to perform paracentesis. Her husband held her while I punctured the drum membrane in two places with a fine Graefe knife, previously applying a four-per-cent. solution of cocaine to the drum. I was successful in letting out considerable pus, and upon inflating the ear by the Politzer method I removed

much more. I recommended warm water to be syringed in the ear three times a day, after which drops of peroxide of hydrogen: also warm applications to the ear. Salt I prefer in a linen bag, if one has not a hot-water bag.

Two days later the patient reported to me that the discharge had ceased; the sixth day the drum membrane had entirely healed. There had been no pain since the morning after the operation. As the patient was on the eve of her departure for a trip South, she could not call on me again, but promised to notify me the following month if similar trouble came on at a certain period, which she did, saying: "A day or two before my monthly sickness I used warm salt to my ears at bedtime and during the day; also inhalations of the menthol preparation you gave me; and am pleased to report I have not been bothered with the pain as before. I find the inhalations of hot medications most efficacious," etc.

Mr. B—— wrote me, June 1st: "My wife every month feels some slight twinge or pricking pain in her ears, but aborts the same immediately by following the orders given her in February. She takes a great deal of outdoor exercise and horseback riding, and feels splendid in every respect."

I desire to say further that when the patient first came to me I examined her nose and throat; they were in a normal condition, but during menstruation there was a general hyperæmia of the nose and nasopharynx.

My opinion in explanation of the condition of the ear trouble is that it was sympathetic to the menstruation—an excessive hyperæmia of the ear, the result of engorgement of the blood-vessels; a vicarious menstruation, so to speak; the first case of the kind I have met with. The large majority of actions which are spoken of as vicarious bear no such relationship to the suspended activity, but are pathological phenomena.

HYSTERIA WITH COMPLETE ANÆSTHESIA AND CATALEPSY.[1]

By CHARLES E. NAMMACK, M.D.,

ATTENDING PHYSICIAN TO OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

History.—Edith B——, twenty-one years old, born in the United States, of Hebrew parentage, applied for treatment on account of "loss of feeling," and gave the following interesting history: Eight years before she had accidentally run a broken and rusty needle into the back of her left hand. The next day the hand swelled, was incised, and the fragment of needle removed. Phlegmonous cellulitis set in and recurred again and again, the hand refusing for four and a half years to heal completely. She visited clinic after clinic, until finally she came under the care of a surgeon who recognized the neurotic element in her case, and, by hypnotic suggestion, cured the hand in about four months' treatment. She stated that she had been hypnotized every day during this period, and that she finally became so susceptible that to gaze steadily into another person's eyes is now sufficient to bring on the hypnotic state. This latter statement was verified on the spot by the senior clinical assistant and, on her next visit to the dispensary, by the writer. This susceptibility is very embarrassing to the young lady in street cars and in public places. Whatever element of attraction these attacks may have had for her in the beginning has long since passed away, and she is now keenly alive to the discomfort of her disease, and resists, with all the will power she has, the influences which induce the hysterical state, which latter now threatens her future welfare and happiness. She is not presented before you in a melodramatic but in a scientific spirit, and with the hope that a free discussion of her case will evolve a plan of treatment which may make for her complete recovery.

Etiology.—Into the etiology of her case, indirect and dissimilar heredity may enter. Her parents and immediate ancestors have been hard-working Jewish people of the orthodox tenement-house type, overworked, underfed, and badly housed. Their management of the daughter's attacks has been based on the idea that she was possessed of a devil which needed vigorous exorcising, an idea which has the backing of a venerable historical position. But to-day we know that traumatism followed by long-continued suppuration and suffering needs neither demoniac possession nor congenital or hereditary taint in order to lead to depression of the nervous functions and of general nutrition great enough to produce traumatic neurosis, and, as regards its symptomatology, traumatic neurosis does not differ from hysteria. How much the application of hypnotic suggestion aided in the development of hysteria in this case is a question that should be given thoughtful consideration.

Symptomatology.—In the intervals of her attacks the most striking symptom is the alteration in sensibility, *i.e.*, anæsthesia. The anæsthesia appears to be total and universally distributed. Analgesia, or loss of the perception of pain, was noted in every part of the body tested. Anæsthesia, or loss of the tactile sense, can be easily demonstrated with the eyes bandaged. Thermo-anæsthesia is shown by the hot and cold water tube test. Electro-anæsthesia exists. Sensations of numbness, cold, or tingling ("paræsthesia") have not been noted by the patient, in either hands or feet. Dysæsthesia, a condition in which the skin cannot bear the least contact or the slightest change in temperature without experiencing pain, does not exist. Tickling the soles of the feet does not excite reflex action. The nipple reflex persists. The pupillary reflex is present and prompt, both to light and to accommodation. Punctures made to test sensibility do not bleed as in healthy individuals. The mucous membranes of the nose, mouth, and eyes share in the general anæsthesia. The skin of the lids, the conjunctiva, and the cornea itself are devoid of sensation. Hysterical blindness has never existed. Narrowing of the visual field was not tested for. The acuteness of the sight was unaffected. It is doubtless by strong stimulation of the retina that the hypnoid state is produced in this patient and that a bright light would have the same effect as a voluntary concentration of her gaze. Disturbances of taste, which render all food insipid and add very much to the annoyance of patients, are not present in this case. The nasal mucous membrane is affected in the general anæsthesia. The sense of smell is normal. Deafness does not exist, nor does any evidence of impaired hearing. The skin of the external auditory canal shares in the universal anæsthesia. Patient states that she feels the passage of urine and fæces. Sensibility of the genital mucous membranes was not tested. Abolition seems to be the only disturbance of sensation present in this case, there being neither perversion nor exaltation of function. The existence of hysterogenic zones could be demonstrated, as pressure on the ovaries arrested one of the attacks. The painful stigmata of hysteria were absent. There was no perceptible weakness of the voluntary muscles on either side, and dynamometric pressure was fairly good in each hand. The reflexes at knee, elbow, and wrist were exaggerated. The only tendency to contracture observed was the muscular rigidity present during the attacks induced by hypnotic suggestion. Deep massage, taps on the tendons, compression of a nerve, the application of a vibrating tuning-fork, faradization, the ap-

[1] Patient presented before the section on neurology, New York Academy of Medicine, October 22, 1897.

plication of a magnet, and simple touching of the skin, were alike powerless to initiate contracture. The history of the case does not include spasms of the œsophagus or of the neck of the bladder. Blepharospasm, nystagmus, and ptosis are absent. Tremor of any description is not discernible. Her general nutrition, appetite, and digestion are normal. Regarding her mental state, the writer's emphatic conviction is that simulation and deceit do not enter into the manifestations of her malady, but that these manifestations are caused by a weakening of the nervous functions against which she is at present powerless.

Leaving then the persisting or permanent phenomena of her case, we consider next the paroxysmal symptoms. Convulsions do not constitute a prominent feature, although at the menstrual epoch she is apt to have explosions of irritability coincident with slight pain in the ovarian region. The classical convulsive stage with aura, globus, and sensation of constriction in the pharynx is short and abortive, and the patient passes rapidly under the influence of hypnotic suggestion into the epileptoid stage, with irregular respiratory movements and stertor. The extremities execute slow movements for a short time, then follows a general tetanic spasm, sometimes amounting to opisthotonos. Then succeeds a stage of muscular resolution, followed by a period of attitudinizing or "clownism." The attitudes may be illogical, emotional, or passional. A fourth period follows, that of delirium, varying according to the ordinary state of sensibility of the subject. In coming out of the stage of delirium, this patient does not return wholly to the normal condition, but is usually able within two hours to go home unassisted.

She thus presents all the phenomena of the "grande hysterie" of Charcot, a form which is not common in this country, although physicians who practise among the uneducated Polish Hebrews of this city meet it frequently. Fear, superstition, and the faculty of imitation form powerful auxiliaries in the development of neurotic tendencies in these people to the overwork and privations which pull down their physical development and pave the way for neuroses in their children.

But in addition to the ordinary symptoms of "grande hysterie," the stage of attitudinizing in her case exhibits a marked degree of catalepsy. Her limbs may be mechanically placed in attitudes which remain fixed, but the fixity of the attitudes is not absolute, for the limbs finally obey the laws of gravity at the end of a certain period. Somnambulism and ambulatory automatism have never been noticed in her case, in which latter respect she is more fortunate than the patients whose case is mentioned by Desplats. (Reference in *New York Medical Journal* of October 9, 1897, page 506.) Memory has not been impaired. The nutrition of the skin has not suffered recently to the extent of producing dermatoses, excesssive sweating, localized œdemas, spontaneous urticarias, dermographism, pemphigus, ecchymoses, or hemorrhages, but she gives a history of one attack of blue œdema and frequent limited urticarias in the past. The hair and nails present no abnormalities, nor is there unnatural dryness of the skin. Hysterical breast has never occurred. There is no muscular atrophy at present. The writer has no reliable evidence regarding the presence or absence of hysterical pyrexia during the paroxysms. She gives a history of motor paralysis affecting the right upper extremity and left lower extremity simultaneously, which was cured by suggestion. The systematic palsy of the movements necessary for walking and standing, known as astasia-abasia, has never existed. Disorders of speech, like mutism, occurred once in her history, but her voice returned in three weeks. Respiratory spasms, such as cough, barking, hiccough, sneezing, and aphonia, have not been prominent, although the patient at present complains of a weakness of the voice which prevents singing. Laryngoscopic examination does not reveal any local lesion. Digestive disturbances, usually very frequent in the hysteria of young women, occasion no complaint in this instance, except the spasm of the pharynx which forms a part of the first period of the attack. Dysphagia, gastric spasms, vomiting, gastralgia, hæmatemesis, hysterical anorexia with its "excess of resistance aroused by an excess of insistance," have formed no part of her clinical history. Meteorism, constipation, intestinal colic, diarrhœa, or rectal tenesmus has not appeared. The urinary apparatus is not the seat of any trouble. Wandering kidney, regarded by Féré and by Albarran as a stigma of degeneration, is not demonstrable. Polyuria, independent of the attacks and permanent in character, and ischuria coinciding with vicarious vomiting, are alike wanting. Retention and incontinence of urine are absent.

It seems important to insist here upon the fact that "some of the traits of character so often ascribed to hysteria by former writer, such as simulation, sexual perversions, scruples, and morbid impulses, are symptoms of degeneracy and not of hysteria" (J. Hendrie Lloyd, "Nervous Diseases by American Authors," page 129). It will be observed that such symptoms play no part in the history of this girl, who is only anxious to do her full duty as a daughter or wife, and does not seek to attract attention to herself.

Too many medical men still regard hysteria as on a level with folly, mendacity, and malingering, and treat it in accordance with that idea. It cannot be too frequently repeated that physical rather than mental agents play the predominating rôle in the causation of hysteria. The mind is not an organ but a function, and this function is troubled whenever its chief organ, the brain, does not receive nourishment which is proper in quantity and in quality, or whenever it is unduly fatigued. To this conception must of course be added that of congenital defect as a personal factor in the causation of hysteria, as of other diseases.

42 East Twenty-Ninth Street

CLINICAL MISCELLANY.[1]

By R. ABRAHAMS, M.D.,

District Physician to Mount Sinai Hospital, New York.

In selecting material for this paper, my aim was to present to your attention a series of clinical pictures, though varying in theme, yet I hope interesting and instructive.

Post-Partum Eclampsia Followed by Hemorrhage.—It was in the fall of 1895, when I was called to deliver Mrs. G—— of her ninth child. I had delivered her twice before. She is a short, puny, little woman, about thirty-five years old. For four years she frequently suffered from intense uræmic headaches and gastro-intestinal disturbances consequent upon an old Bright's disease. Her heart and lungs, liver, and eyes were in good order. Her urine always contained some percentage of albumin and different kinds of casts. At no time, whether she was pregnant or not, were her legs or face œdematous. At my arrival I found a midwife, a stillborn child, and a placenta half way out. I was informed that the labor was rapid and the child was born dead, and that in spite of all efforts at resuscitation it remained dead. All was serene and comfortable after the placenta was expressed and sundry minor things were attended to. Just as I was about to leave the room, a half-hour after the completion of the third stage, I noticed that the patient was getting ready

[1] Read before the Society for Medical Progress, November 10, 1897.

for an eclamptic fit. Two typical paroxysms occurred in rapid and terrible succession before I could send out for help and drugs. No more than three minutes after the second seizure, just as the coma was deepening, a violent uterine hemorrhage appeared, blanching the patient as well as the medical attendant. It would be taxing your patience if I told you in detail how the woman looked and felt, as you can all easily picture her condition: suffice it to say that she was alive with a pulse scarcely perceptible. The treatment might be of greater interest. The poor, filthy, wretched surroundings only intensified the gravity of the circumstances. Grabbing the first and nearest rag within reach and view, I shoved it up into the uterine cavity. When that organ was effectively packed, the horny hand of the husband was put on it. Next, about three quarts of saline solution was pumped into the rectum and colon, which was fortunately retained; then came the liberal use of ergot, strychnine, and whiskey hypodermically—never mind the dose. In about twenty minutes the woman began to rally, the pulse and color grew better. The coma had disappeared, as the patient yawned and sighed and tossed about, symptoms characteristic of loss of blood. In three hours I felt secure to leave her to the care of the untrained nurse. At my visit the next day the woman was found pale yet comfortable, pulse rapid but of good quality, and the uterus firmly contracted. The packing was slowly removed, followed by a hot sublimate irrigation. The woman made a good recovery: was up in ten days. During the puerperium intense headache was complained of and pain in the right thigh. This latter trouble resulted from the hypodermic needle and eventually terminated in a mean, nasty abscess which took some time to heal. Aside from this uncommon though not impossible complication of events, two points might be of interest and utility: (1) The magic effect the saline injection exerted on the pulse. It was immediate and salutary. It was quite evident to me, as I anxiously watched the dying woman, that all the employed stimulants added auxiliary aid only. (2) The cessation of the eclamptic fit and the emergence from coma after the hemorrhage. This observation would tend to lend support to the practice and doctrine of some that venesection benefits puerperal eclampsia.

Death Resulting from Diphtheria Antitoxin.—In the early and struggling days of antitoxin, when every shaft of criticism was hurled at it by its few but loud opponents, a physician with a small quantity of serum but a large quantity of enthusiasm was vociferously decried for refusing to waste his precious drug on a moribund diphtheritic child which held out no other hope but that of adding a case against antitoxin and fuel to the flame of prejudice. At that time this action and refusal were eminently just. Now, however, as adverse criticism, no matter the source, could not alter the universal verdict of the almost uniform beneficence of diphtheria antitoxin, one need not fear bias or intimidation by reporting a fatal case resulting from its administration.

Child, F——, six years old, developed tonsillar diphtheria on a Friday. Saturday, about five o'clock in the morning, I was called because croup appeared. The child was examined: diphtheritic membrane was found covering the tonsils. During the day the parents made an effort "to scrub off the white blisters." Although the child was decidedly croupy, the breathing was far from alarming. Temperature, 102 F., with a pulse in proportion. At half-past six o'clock I injected between the shoulder blades fifteen hundred cubic centimetres of the antitoxin of the New York board of health. The reaction was marked by a rise of temperature of one degree, otherwise the child fell asleep, as most of them do after serum treatment. At eleven o'clock the temperature was the same, but there was evidence of improvement in the breathing and the cough. Nourishment was taken without protest. At one o'clock the report was still more gratifying. At two o'clock the child suddenly began to gasp for air and became very blue, with cold extremities, poor pulse, and profuse cold perspiration. This alarming condition lasted but ten minutes. Then the child began to breathe quietly, pulse weak, and temperature subnormal. A slow but gradual paralysis of the limbs and reflexes set in, and by five o'clock, in spite of the most vigorous treatment, the child died in a condition of total collapse and paralysis. The most curious feature of this case was that the quiet though slow breathing was preserved until the last moment, and, were it not for the ghastly appearance of the face, one could not by mere inspection tell the approach of death.

There is no doubt in my mind, and in that of another physician whom I showed the case, that the antitoxin was responsible for the speedy and fatal termination. It was not a case of profound septic diphtheria, and the fact that improvement followed the injection but fatality later should urge the physicians to watch their cases, instead of being, as some are, satisfied that they have done all they can after making the injection, and trusting that a beneficent Providence will look out for the rest.

Gummous or Tertiary Bubo.—The adenitis which accompanies the initial lesion is so common that one instinctively looks for it in examining a suspicious ulcer; indeed, its invariable accompaniment, coupled with its characteristic features, often helps to establish the true luetic nature of the ulcer. The adenitis which appears in various regions of the body during the evolution of the secondary stage of syphilis, though less universal, is not less known. So are glandular tumors known to occur coincidently with ulcerating gummata years after the acute stages of the infectious process. But instances of isolated syphilitic bubo, wholly independent of any sign of existing syphilis, primary, secondary, or teriary, are excessively rare. Upon this point I beg to quote Dr. S. Lustgarten (Villarets' "Dictionary of Medicine," article "Bubo," New York MEDICAL RECORD, January 11, 1890), who, more than any other, brought this subject most prominently before the profession here and abroad. He says: "Nearly all of the cases mentioned, as well as a number of those which follow, contain instances of gumma of glands complicating other tertiary process. The observations of glands affected in an isolated manner are of more importance, but are much less frequently referred to (about twenty cases, including my own four observations). If the first group demonstrates by the complication the syphilitic nature of the affection, and removes every doubt of its existence, the second is of more importance, because it shows the difficulty of diagnosis in some cases and the clinical resemblance to malignant tumor, and especially to malignant lymphomata." A typical case of an isolated tertiary bubo came under my observation last summer in June.

Miss L——, twenty-five years old; prostitute. Nothing known of her family history. Appears in perfect health. Denies specific disease. For five months she noticed a gradual, painless enlargement of the glands of both sides of her neck. As the swelling did not hurt her she did not care to doctor about it. She consulted me because the tumor on the left side of the neck assumed such dimensions that it interfered with the natural movements of her head. A careful examination was made of all the internal organs, with negative result. The teeth were found in good condition. No skin trouble: hair and scalp healthy: no anæmia and no enlargement of any other glands of the body, except those of the neck. The latter appeared

on the left side as one conglomerate mass, commencing at the mastoid process, coursing along the line of the sterno-cleido muscles, and projecting far to the median line. Upon careful palpation of the mass one could distinguish separate glandular nodes, small in size but adherent to the main mass. The tumor on the left side was considerably smaller in size; its separate constituents were more distinct and separable. The tumors were somewhat movable and the skin overlying them was considerably so. At the lower end of the left enlargement there were slight fluctuation and a mild redness of the skin. These two features were considerably augmented by the application, through mistaken orders, of hot linseed poultices. In three days I was tempted to incise that part of the mass which appeared suppurative. A few drops of sero-purulent stuff escaped. The healing for a week was unsatisfactory. The edges of the wound were thin and everted; the cavity was not large but yet not healthy in appearanec. Up to that time, while different diagnoses suggested themselves, none appeared plausible. However, it is said that a man is judged by the company he keeps. I judged this woman's lesion by the pathological mishaps her profession entails. I therefore empirically put her on large doses of iodide of potassium, mercurial plaster, and inunctions. In a week improvement began to show. In four weeks there was no vestige of the tumors. This remarkable result left no doubt in my mind that the tumors were of the variety named by Dr. Lustgarten, "gummous or tertiary bubo or lymphoma."

Dislocation during Birth.—The subject of dislocation in children is interesting on account of the rarity of the occurrence, and in infants it is doubly interesting, because the rarity is still greater. Scanzoni is quoted in Keating's "Cyclopedia of Diseases of Children" (page 1,099, vol. iii.) as saying that he "never met with luxations in the newly born, yet they occur sometimes as congenital lesions, sometimes and not seldom in the hip as the result of powerful traction made on the lower extremities." The three cases of luxation that I will briefly report belong to the latter class.

Case I.—Infant B——; mother was delivered by a midwife. Primipara: breech presentation. In delivering the after-coming head, tremendous force was applied in traction on the legs. Two days later I found the right buttocks swollen with limited motion. Diagnosis, downward dislocation of the hip. Reduction accomplished by manipulation; no anæsthetic.

Case II.—This case was one of double dislocation of the lower jaw, brought about by an effort to deliver the after-coming hand. It was effected by making traction on the lower jaw with a hand in the vagina; the other hand was employed in pressing the occiput. The accident might be attributed to haste, impatience, or a false notion of obstetrical mechanics, but the result was instructive. Reduction was accomplished without trouble.

Case III.—Those who practise among the ignorant foreigners are undoubtedly familiar with a pernicious practice religiously performed by mother, midwife, or nurse, for some time after the birth of a child. I refer to that manipulation technically described by them as "measuring the infants' limbs" in or out of the bath-tub.

Infant C—— had his limbs kneaded and straightened in its morning bath. Shortly after the mother found that it could not nurse, and it also "checked" in swallowing. An examination disclosed an upward dislocation of the sternal end of the clavicle. The accident and its removal were beneficial to both mother and child—one learned a lesson, the other obtained relief—then and for all time to come.

The last case of this clinical hodgepodge is one of amusing interest. You know it has come to pass that there is no medical gathering without the mention of appendicitis. I shall therefore relate a case of what one might call pseudo-appendicitis.

A married man of twenty-eight years, an hour or two, or perhaps longer, after feasting sumptuously on poultry, began to complain of pain in the abdomen. The pain was not violent but rather constant. Vomiting and fever were absent. Gradually the uncomfortable feeling shifted to the right iliac fossa, the Mecca of modern surgeons. The man stayed home, though not in bed. From Wednesday evening to Saturday morning there was decided tenderness in the appendiceal area, but nothing else. Early Saturday morning he treated himself to a good dose of Epsom salt, which produced several movements. After the last passage he found himself riveted to the seat. The pain at the anus was so intense that he was carried to his bed. Examining the seat of trouble, I immediately discovered the difficulty—a chicken bone, about an inch and one-half in length, with rugged edges, was placed firmly and squarely across the anus. It required force to remove the bone of contention, as it were. After this the patient made, as the stereotyped phrase goes, an uneventful recovery. All pain in the right iliac fossa ceased at the escape of the bone. It seems to me reasonable to infer that the bone, in all probability having lodged in the caput coli, produced a condition simulating a mild catarrhal appendicitis. If there is anything in the "inductive method," this supposition is correct.

SUDDEN DEATH IN ACUTE RHEUMATISM—MAMMARY CANCER—SIR W. JENNER — PRINCE'S FUND AND PROPOSED CENTRAL BOARD—THE COLLEGES ON ARMY MEDICAL REFORM—MR. ALLINGHAM—THE LATE CARMATT JONES—INFLUENZA AND DIPHTHERIA.

London, February 4, 1898.

The subject of sudden death in acute rheumatism was discussed by the Clinical Society on Friday, *à propos* of a case related by Dr. Heringham, in a girl of sixteen. The joint pains ceased under salicylate of sodium, but she continued to suffer pain in the epigastric and precordial regions, and became cyanotic. The heart enlarged, râles became audible, and fever persisted until a sudden change occurred and she died in a few minutes. At the post-mortem œdema of both lungs was found, with fatty degeneration of the walls of the left ventricle and great increase of cells in the interstitial connective tissue—acute myocarditis.

Such an acute change in the heart is perhaps the usual cause of sudden death in the few cases of rheumatism terminating in this way. It would scarcely be possible to diagnose it, but suspicion might be excited by cyanosis without sufficient lung mischief to account for it, especially if accompanied by pain in the precordia.

Dr. Maclagan said the best account of such cases was Corvisant's, who scheduled them as "distinct" and "latent," according as there was any evidence or not of direct changes in the heart. When there was not, the symptoms were referable to the nervous system. He believed that inflammation spread from the pericardium to the endocardium, but not in the reverse way, and said that endocarditis never spread all over the heart, but was limited to certain spots. He never

gave salicylate of sodium when he suspected the heart, but used salicin in such cases.

Dr. Lees said he was indebted to the author for the details of the post-mortem, and he wished that in every fatal case of rheumatism the cardiac muscle could be examined microscopically. He had come to believe in definite enlargement of the heart apart from pericarditis. In one case the progress of recovery was watched by tracings made without reference to those taken on the preceding day. They showed at first great dilatation, which rapidly diminished to normal under treatment. He considered that the symptoms—delirium, pain, dyspnœa, cyanosis—did not prove cardiac inflammation, but might be due to the toxic action of rheumatism.

Dr. Glover described the post-mortem appearances in the case of a man of fifty, who died suddenly the first time he was visited. There was a reddish or grayish-red patch, the size of a five-shilling piece, on the front aspect of the heart, looking as if it might have sloughed out, with a corresponding patch on the opposing surface of the pericardium. Another spot on this membrane was ecchymosed. Discolored clots were found in the aorta and pulmonary vessels. The lungs were congested and emphysematous.

Dr. A. Morrison remarked on the common experience that the initial evidence of cardiac failure first manifests itself in the left lung.

Sir D. Duckworth said he had seen endocarditis pass bodily into the substance of the heart. It was ushered in by progressive failure of the circulation, and was sometimes averted by treatment. He thought salicylate should be discarded in such cases for iodide of potassium, quinine, and a stimulant.

What is the general result of operation for cancer of the breast? This is perhaps the principal question suggested in the discussion by the Medico-Chirurgical Society, evoked by Mr. Marmaduke Sheild's paper, entitled "Immunity and Latency after Operations for Reputed Cancer of the Breast." Mr. Sheild had collected and tabulated a number of cases from various sources. These cases seemed to show that the results of the older operations were not so constantly bad as is too often declared by advocates for the more extensive procedures now commonly adopted. In one group of cases forty-four were recorded in which there was no recurrence after long periods; but in the same group there were sixty-four recurrences. In some cases these recurrences were repeated, and in others there was immunity for very long periods. Mr. Sheild submitted that some of the results must be due to peculiarity of the growth or of the patient, rather than to the extent of the operation. Volkmann's rule of a three-years' limit was evidently too absolute. A much longer period must pass before admitting a "cure." A collective investigation was suggested as to the results of the old "incomplete" or the newer more extensive operation. Objection was taken in the course of the discussion to the terms complete and incomplete—the latter of which almost suggests the omission of something which the surgeon ought to have done.

Mr. Pridgin Teale had a record of private cases for thirty-five years. In eighteen selected cases there was only one recurrence in eight years, but all but two or three of the patients eventually died from this cause. In his earlier work he had not systematically opened the axilla, but later had done so and removed all glands that could be felt. He had not removed the pectoral fascia. He repudiated the term "cured" for cases operated on. The extensive operations recently done, he said, would have led to greater mortality before the antiseptic period.

Mr. Bryant thought the statistics submitted enabled operators to give a more favorable prognosis, as some patients had survived from five to twenty years. Of his own private patients, seventy-two in number, fifty-five per cent. died within three years, forty-four per cent. lived longer, twenty-two per cent. for five years or upward. He cleared the axilla and removed the pectoral fascia only when necessary, but he always opened the axilla to see if the glands were enlarged. Still he found that recurrence, when it took place, did not generally do so in the line of the lymphatics. The results of the so-called "incomplete" operation were better than those of the more extensive. These last on old women would raise the mortality. Nodules might come and disappear again, leaving white scars behind, as he had seen in ten cases.

Mr. C. Heath said he still took care to remove all implicated tissues, with results as good as those claimed for more extensive operations.

Mr. Barwell had had a patient who survived for twenty years, another fifteen, and six patients who died from other diseases after ten years without recurrence.

Mr. Butlin protested against the pessimism that there was no cure for cancer. It was "fatalism and the high Calvinism of surgery to say, Cancer once, cancer always." He accepted Volkmann's three-year limit as a fairly useful one, for if no recurrence occurred in that time the patient might be said practically to be cured. If the period should be somewhat longer for cancer of the breast, it might be shortened for some other parts, *e.g.*, the tongue; and, as experience increased, he thought the time limit of every organ might be fixed.

The further discussion of the subject was at this point adjourned.

Sir William Jenner arrived at his eighty-third year on Sunday last. He retired to his country seat some years ago. He is remembered by his old pupils with intense respect as their ablest clinical teacher. A good story is told about his son at Oxford. A cleric, on being introduced to the young man, asked if he was any connection of "the great Jenner," and on being asked in return which Jenner he meant answered: "Why, the bishop, of course." There were those present who had not heard of the bishop.

The Duke of Bedford presided at the dinner of University College Hospital on Wednesday. He deprecated any attempt of outside persons to interfere with the control of the hospital.

Mr. Christopher Heath, in returning thanks for the staff, took the same stand and showed that the plan of the Charity Organization Society would hand our hospitals to a body having no responsibility for their pecuniary support.

My recent remarks have not pleased the Charity Organization Society or the advocates of its central board, and the *Medical Press and Circular* opines that I am not "inspired" as to the Prince of Wales' fund. He says, "Up to a certain point these remarks are quite true," and then goes on to speak of the other funds. I made no claim to be "inspired," though I had unimpeachable information on the points raised. But I do not hold a brief for either of the funds.

The presidents of the two Royal Colleges have sent a joint letter to the war minister, urging that the demands of the medical officers of the army should be granted.

Mr. Herbert Allingham has been appointed surgeon to the Prince of Wales' household.

Mr. Carmatt Jones, F.R.C.S., died on Wednesday, in his fifty-first year. He was an enthusiastic worker in his specialty—rhinology—and the advocate of "spoke shaving" in nasal surgery, a procedure which has excited much difference of opinion.

Influenza still prevails. The type is mild, but there are malignant cases. The weekly mortality has steadily increased, as follows: 15, 29, 43, 40, 73, 88.

The disease has also appeared in many country districts.

Diphtheria is still on the increase in London. Thirty-six deaths from this cause were registered last week. The admissions into the asylums boards hospitals were 161, and 1,055 cases remained under treatment.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE MEDICAL PROBLEM—A CRISIS—OVERCROWDING—DEATH OF DR. PÉAN—TREATMENT OF BURNS BY PICRIC ACID—PAINS AND SYMPTOMS OF POISONING CAUSED THEREBY—ABANDONMENT OF THE TREATMENT.

PARIS, February 8, 1898.

THE overcrowding of the medical profession, not only in Paris but also in New York, is really a burning question, and almost every day it is brought home practically to its members and the public. All the trouble in New York regarding the dispensaries, and in Paris regarding the rigorous laws upon the practice of medicine and the admission of foreign doctors and students, has its origin in this plethora of medical schools and colleges, professors, physicians, and their pupils. The cause is easy to find—we have it right there: but the remedy—"Ay, there's the rub." In France it is boldly asserted that there is none, and a large proportion of those already engaged in the practice of medicine or about to embark upon it must go to the wall. It appears that a veritable medical crisis has been reached in France. A writer in *Le Figaro*, the great French literary journal, informs us in a recent number that he found upon his table a medical sheet containing the letter in which a physician announces to the inhabitants of Gergy that he is obliged to leave them, because the prefect has just cancelled an appropriation of only 200 francs in his favor—and he pointedly adds that medicine, at the time that it makes princes, tends to make *prolétaires*.

Let us look for a moment at the actual facts and figures. There are the doctors in the French senate and chamber of deputies, principally the latter; there are the electricians, masseurs, and hydrotherapeutists, whose number is very considerable—the number of physicians in the Parliament being estimated at eighty. Now if all these were thrown back into the great general medical profession, the crisis would be still greater.

There are twenty-five hundred physicians in Paris alone, and of these I have it on undoubted authority that twelve hundred barely make enough to live upon. Of the ten thousand provincial doctors, five thousand are in a pecuniary situation about equal to that of the conductor of a surveying-party. Of the other five thousand nothing is said; but one can easily imagine their financial and general condition when it is remembered that the country hardly nourishes its physicians, and a number of communes can get one only on condition of voting him substantial aid. Professor Lannelongue, president of the General Association of Physicians of France, announced recently to his confrères the approach of a time when the average receipt of a doctor would not exceed 3,000 francs, or about $600 a year—a sum so very small that it is not the interest on the capital expended in obtaining a medical education in France. And, in spite of oft-repeated statistics, we still find foreign doctors, Americans especially, anxious to practise here. As for the students in medicine, why, their number has more than doubled since the war of 1870, rising gradually and steadily from four thousand to eighty-four hundred and eighty-five.

Large numbers of the profession, both in New York and Paris, are aware of the actual truth regarding their chances of success in such a professional ocean, and seek municipal or State positions. We know how many applicants there usually are in New York for the most modest medical post within the gift of the authorities, and we also know exactly how such positions are obtained. The same holds good in France, where the faculties graduate twelve hundred doctors a year, and there are but six or seven hundred vacant posts to fill.

One cause of the trouble in this country is that young men become doctors or licentiates to avoid military duty—that is, to do one year's military service instead of three; and that explains also, in part at least, the success of shady clinics and the painful contact of medicine with the criminal courts.

We have just sustained a loss by the death of Dr. Péan. After all, perhaps the laity is the best judge of the doctor and the man; not of Péan especially, but of all doctors. To satisfy the public, to have the public appreciate a man at his real value—that is the crucial test, that is the practical refinement of professional dross. Péan was a great surgeon, a great and good man, a field marshal of French surgery—that is the verdict upon the man, large of heart and body, always lending a helping hand to his younger, struggling confrères, actively engaged in works of charity, continually giving his services gratuitously to the poor, and at the moment of his death considering, with other distinguished physicians and surgeons, the means of brightening the clouded future of the medical profession. Péan was a member of the more important academies of medicine all over the world, and was a commander and grand officer of orders innumerable. His famous debate with Verneuil, about the small hæmostatic forceps, or "pinces," as he called them, is still fresh in memory. As soon as he felt the rigors of pneumonia upon him, he said to his friends, "I am lost;" and, as the disease progressed, he added, counting his own pulse: "I never knew any one to survive what I am experiencing. In an hour I shall be dead."

The local treatment of burns by picric acid has received its *coup de grâce*. At least, it will probably not in future have that popularity in hospitals and private practice that it has hitherto enjoyed. Dr. Walther, at a recent meeting of the Society of Surgery, introduced the subject, *à propos* of two children, of eleven and four years of age respectively, who had been burnt to the first and second degrees. Dr. Latouche, at the Autun Hospital, dressed the burns with a saturated watery solution of picric acid. Five minutes after the children complained of lively pains *in loco*, lasting about an hour. Five days after, when the dressings were removed, the surfaces had a good appearance, with a slight suppuration in the younger child's case. A second dressing with the same solution of picric acid caused the same pains as the first. The third dressing was made with picrated vaseline, ten parts to one hundred—each child getting about two hundred grams of the ointment, or twenty grams of picric acid. This time the result was deplorable. Violent pains in the wounds, and lasting three hours, were followed, twelve hours later, by incessant vomitings, active colics, yellowish diarrhœic motions, with tendency to coma, general icterus, and scanty black non-albuminous urine heavily charged with picric acid. This serious condition disappeared only after two days in the case of the elder child, and after eight days in that of the younger. In both the urines remained black for several days, the burns healing in about twenty-five days.

Dr. Berger, who has had grave annoyances, often persistent pains, with picric acid in the treatment of burns in children, has abandoned that mode of treatment altogether; also Dr. Tuffier, who alleges that

the treatment causes pains, pigmentation of the skin, and eczema. Dr. Championnière has seen intolerable pains and a certain intoxication caused by picric acid in cases of burns. Dr. Hartmann has observed intense erythema and pains provoked by picric acid in the adult. After this, we may at least say, picric acid as a dressing for burns of the first and second degrees is not likely to supersede the good old plan of powdering with dry bicarbonate of sodium or dressing with linseed oil and lime water.

A MODIFIED INCISION AT THE OUTER BORDER OF THE RECTUS MUSCLE FOR APPENDICITIS.

To the Editor of the Medical Record.

Sir: The excellent literary standing of the Medical Record and the deserved prominence given in a recent number to the article by Dr. Kammerer on "A Modified Incision at the Outer Border of the Rectus Muscle for Appendicitis," I think are sufficient warrant for a slight criticism of his anatomical assumptions. The nerve supply of the rectus abdominalis is through the lower intercostals and not through the ilio-hypogastric (incorrectly spelled ileo-hypogastric), which is chiefly or exclusively a cutaneous nerve. Also his assumption that an atrophied spot in the rectus was between two lineæ transversæ has but scant probability, since these vestigeal abdominal ribs are not scattered at random throughout the length of the muscle but are usually three in number, the lowest at the umbilicus.

H. L. Hibbard, M.D.

MIDWIVES AND THEIR DISREGARD FOR ANTISEPSIS.

To the Editor of the Medical Record.

Sir: A few days ago I was hastily summoned to a woman who had given birth to a child seven days before. Her husband called, stating that his wife had "pains in her stomach," and had been crying for the past six days, and that a midwife was in attendance. I immediately answered the summons. Upon my arrival at the patient's house I heard groaning and heartrending cries, which were being uttered by the patient, a woman twenty-two years old.

Questions put to the patient elicited the following: A midwife delivered her of a healthy child "without any trouble" (vertex presentation). Twenty minutes later she expressed the placenta, which came away complete. No hemorrhage. Twelve hours after delivery the patient complained of severe pains, which the midwife diagnosed as after-pains. The husband, not being satisfied with the explanation, summoned a physician who happened to pass by. Examining the patient, he found a temperature of 102.6 F., pulse of 96, tenderness over the entire abdomen, and localized pain on the left side. He advised currettage, but the persuasive words of the midwife "to wait" were successful, and only intra-uterine irrigations with creolin were ordered, which the midwife promised to make, and did make as promised. Five days later I was summoned to attend the patient, who not only was getting worse but also was exhausted from constant pain.

A thorough examination was made, the result of which was to disclose an unquestionable septic endometritis with pelvic cellulitis. While I was examining the patient the midwife appeared, somewhat astonished at the present status and proceedings, and quickly assured me that there was nothing wrong, that the patient only had after-pains (seven days after delivery)! Wishing to make an intra-uterine irrigation, but not having the catheter or Chamberlain tube with me, I promised to return in one-half hour, when the midwife, with all her kindness and born friendliness, offered me the catheter which she had used for the patient right along "to make the irrigation, which is so easy." To save time and another visit the same evening I accepted her offer, when to my surprise she opened a small handbag, which, by the way, contained gloves and handkerchiefs, and out came a female catheter, dirty and filthy, used for the withdrawal of urine. Quickly stepping to the hydrant, she washed it with cold water, and in handing it to me she remarked, "Here, doctor, is the catheter. It is clean. I always wash it off before using. It is all right now." Indignation and surprise were at this moment battling for supremacy. What was I to do? What was I to say?

I now ask, is it a wonder that we have so many septic cases after midwives? Shall human lives be sacrificed simply because midwives are careless and ignorant? Should the medical profession allow such proceedings to go on? Is it not high time that such nuisance should be stopped? How many who trust their lives to such ignorant women, for a paltry sum, put them in jeopardy? Is there no remedy to erase from existence such incompetent and careless midwives? What is the legislature going to do about it? Are the just demands of the majority of the profession to be ignored?

Gustav Kompert, M.D.

[illegible] Second Street.

PERSONAL CLEANLINESS AND THE HYGIENE OF PUBLIC CONVEYANCES.

To the Editor of the Medical Record.

Sir: Not only is the part that imagination plays in science evident in the various theories and hypotheses that help modern investigation, but now and then a germinal idea may be traced back to some poet or even to a person of unsound mind, just as years before the invention of the telegraph and telephone lunatics in confinement spoke of messages received from a long distance over wires entering into the walls of their cells. The light that pathological anatomy has thrown upon physiological problems only partly solved shows further the plausibility of such suggestion, which is mentioned here only to introduce the fact that the poet Lucretius long ago wrote of the microbian theory now dominating the minds of modern physicians.

The fight with the infinitely little appears to be the order of the day; we no longer attack disease as a morbid entity, but rather concern ourselves with the sanitary relations of man with the microscopic world and with the means of making these relations contribute to his welfare. In view of the popular interest in much that is written about cleanliness and the sanitation of public conveyances, and the great room for improvement in the conveyances themselves, as well as in the cleanliness of the people travelling by them, I may therefore mention the motive that prompted the detail of incidents coming under my own observation.

Lately a passenger by one of the Eastern Shore steamers plying the Chesapeake Bay from Baltimore told me of his becoming infested with lice, while a number of young women from a fashionable boarding-school in Washington met with the same misfortune in travelling from Chicago on a sleeping-car.

Many persons who served in the late civil war are familiar with this and other forms of parasitism; seafaring people know of vermin-infested ships—for instance, cockroaches on whalers, which I have known to eat one's finger and toe nails into the quick during sleep; and at least one medical man wrote a journal article some years ago concerning the different parasites found in the cushions of street cars and the ferry boats of New York—a circumstance that had prompt

effect in bringing about salutary reform in this respect.

During a residence in Washington I have seen Acanthia lectularia in the herdic cabs and in one of the fashionable churches; but my first experience with pediculi dates from 1866, during the cholera epidemic at Tybee Island, Ga., when I was in charge of the Savannah quarantine. In addition to other annoyances and discomforts of the occasion, I found the old hulk used for boarding purposes infested with lice. Again, in 1878, when a passenger by one of the transatlantic steamers, I knew of several passengers, one of them an Italian count, who had the misfortune to make acquaintance with these unpleasant travelling-companions. From experienced officers with whom I have talked I learn that it is often difficult, if not impossible, to prevent a passenger ship from becoming infested with vermin. The chief officer of one of the ocean greyhounds told me lately that even with the utmost care lice would sometimes spread rapidly through a ship. A person of undoubted veracity, formerly an officer of one of the old "Black Ball" line of packet ships which antedated the present steamer traffic tells me that a ship of that line became so infested with lice that on one occasion on going aloft he found them crawling on the topmasts. Such a story might test credulity, had I not seen them almost as bad on board an English steamer on which I sailed from New York for London in 1882. The first night or two out the passengers complained of being bitten by "mosquitoes" during the night; but every one found out differently before the voyage was over, and the owners were obliged to lay up the ship to be cleaned and fumigated. Still later, on board one of the crack steamers between New York and Liverpool, I knew of a lady of extremely fastidious tastes who, to her great consternation and disgust, became swarming with lice. I could prolong these citations by others learned in Marseilles and in various seaport towns of Italy frequented by merchant vessels.

Government ships, owing to superior advantages for enforcing cleanliness, are of course not so subject to these conditions, although at times such things do happen. When I was surgeon to the Arctic search expedition in 1880, several men and two officers of the *Corwin* became lousy from eiderdown jackets they had purchased from the natives of Saint Lawrence Island.

That birds and other animals of the lower orders are infested with lice that may be communicated to man is a fact not generally known. When serving on the Rio Grande frontier I knew of an army surgeon, something of a taxidermist, who became infested with these unwelcome guests from a pelican that he had killed. On subsequent examination of a number of the birds, I found them all affected by pediculosis. About the same time an officer of the fourth cavalry called my attention to a sore eyelid, which turned out to be ciliary blepharitis from what I then supposed was a crab louse with which his horse was infested. I have since learned, however, that the parasite in question was one lately described in a publication of the department of agriculture.

Dr. Bertellett, of the United States navy, tells me of a case of pediculi palpebrarum that he noticed in a coal passer on board a naval vessel.

Judging from the small number of cases reported, this condition of the appendages of the eye appears to be unusual and all the reporters speak of it as extremely rare, although Celsus mentions a phthiriasis of the eyelids from this cause.

Nor is the condition less prevalent ashore than on shipboard, as most of us know who have travelled much. Discoursing on sanitary science, a Smithsonian lecturer lately said that in the next generation the present Pullman sleeping-car will be on exhibition as one of the insanitary abominations of our forefathers. In addition to other cases I may cite from personal knowledge that of a lady, her son, and a nurse, who lately, in going from New York to Quebec, became infested with lice.

If these unwelcome travelling companions were the only discomforts of the railway conveyance, health would be but slightly menaced; but when we take into consideration the great army of spitters, many of whom are tuberculous, and the accumulated microbian dust of the curtains and carpets of the ordinary sleeping-car, which hold the seed sown by contagious travellers for those who follow, the damage therefrom assumes a reality that cannot be disputed. Indeed, hygienists have so well demonstrated by experiment the contagious properties of dust collected from cars that we may assume as axiomatic the fact that dust is the great enemy of public health. We may further insist upon the fact that cattle are better treated than human beings, since their cars are disinfected after each trip; diligent care is taken to prevent among them the spread of tuberculosis, and it is said that in European armies the medical attendants of the men are numerically inferior to the veterinarians in a regiment of cavalry.

The danger of bringing to light the virulent dust stored up in carpets and the like is one that may persist during a considerable period, since the dangerous germs contained in dry dust left by our predecessors in local habitations have been shown by experiment to live for years. In at least one instance, when the dust was placed in sterilized tubes microbes were found after sixteen years, and among them a very dangerous one, the bacillus of tetanus, which had preserved all its virulence. From such facts the deduction is that dust contaminated by disease germs, especially if kept away from light, is an agent whose action is hurtful to the healthy organism, and ought to be considered as remaining dangerous at least during twenty years.

A question as to the relative cleanliness of Europeans and Americans naturally arises in connection with this subject. The special investigation of the department of labor indicates that Americans are less cleanly than Europeans. Data collected by an agent of the department, who visited the chief cities of the world with the bathtub as his hobby, show with some startling results much to our discredit that Americans are in the aggregate unclean, and, as regards public facilities for bathing, are much behind the old world.

The modern public bath is now found in every progressive European city of any size, but in England, where they have been the thing for more than a century, they take the lead. In Liverpool, with its nine public baths and eighteen sheltered swimming-pools, any one may take a sea-water bath at any season. In one of these establishments, especially for boys, as many as sixteen thousand sometimes bathe in a week. Public bathing-establishments are to be found in two hundred cities of England and Wales, and Glasgow is said to have more bathhouses than any city in the world. The mammoth public-bath establishment of Manchester and that of the Roman Road in East London are the most elaborate of the kind in Great Britain.

Even in Germany, where many people seem proud of the boast that water has never touched their back since the vernix caseosa was removed at birth, we find an awakening as to "rain baths," as they are called. Physicians are beginning to recognize the importance of *Läuse und Läusesucht* in their therapeutic and medical police relations; baths have been adopted in the German army, and forty European cities have introduced them into the public schools, where their use is compulsory. At Stuttgart is one of the most elaborate public baths in Europe. Those of Buda-Pest are also

excellent, while public baths for workmen are fast gaining in popularity among European employers, no less than two hundred baths for workmen being found in Germany alone in connection with shops, mines, furnaces, breweries, etc.

In America, where pure water is cheaper and philanthropy is lavish, public baths open all the year round are found in but two of our hundreds of progressive cities, namely, Buffalo, N. Y., and Brookline, Mass., while the national capital boasts of its bathing-beach alone, where boys are allowed during the summer months to bathe in the sewer-contaminated water of the Potomac. Authentic statistics from eighteen flourishing American cities, which represent a cross-section of the country at large, show that only five-sixths of their citizens have facilities for washing themselves other than afforded by pail and sponge or flowing streams.

From a late report of the surgeon-general of the United States army, we should infer that bathing-facilities for soldiers at most of the posts, though said to be improved, are equally unsatisfactory.

But the crowning report as to American uncleanliness comes from fastidious Boston. The medical inspector of schools, writing to the *Boston Medical and Surgical Journal*, January 20, 1898, reports the prevalence of "Pediculosis in Boston's Public Schools," and says that "some of the teachers had been themselves infected from their pupils as many as four times." An exact idea of the prevalence of pediculosis may be had from the figures of one school of seven hundred and fifty-six children, all girls with the exception of fifty boys, and mostly from respectable families. Of this number but two hundred, or twenty-six per cent., were not infested. A dozen or more of these children showed considerable eczema of the face or scalp and enlarged cervical glands resulting from this pediculous condition. These children being given two weeks to clean up during Christmas vacation, a re-examination of five hundred and nine of them showed the astonishing and discouraging result of only twenty-six children free from nits. Among kindergarten children, less than half had pediculi; the same condition was found in five-sixths of the primary children and nearly three-fourths of the larger girls.

The foregoing facts carrying with them their own commentary, I shall leave the indications of special hygiene and the administrative regulations relatively thereto for others more competent to suggest.

IRVING C. ROSSE, M.D.

WASHINGTON, D. C.

Water Supply of Brooklyn.—The first report of the department of health of the city of Brooklyn, in regard to the sanitary condition of its water supply, has recently been published. This report deals with the question in an exhaustive manner. The water supply of Brooklyn is drawn from sixteen sources, and appears to be very unsatisfactory; in fact, the report fully confirms the general belief that the insanitary condition of a portion of her watershed is a menace to the health of the city. The ponds are stated as a rule to be free from any considerable amount of turbidity, but some of them are decidedly polluted. The suggestion is made that these polluted ponds should be placed out of service. This, however, would cause much inconvenience, as the supply is at present no more than equal to the needs of the inhabitants. That steps should be taken with all possible dispatch to remedy the defects of the existing system is desirable. Undoubtedly, too, the reforms should be sweeping, and rather than to resort to half-measures it would be wiser as well as cheaper in the long run to devise a plan to place the water supply of Brooklyn on a thoroughly satisfactory basis.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending February 19, 1898:

	Cases.	Deaths.
Tuberculosis	199	108
Typhoid fever	9	2
Scarlet fever	172	10
Measles	367	13
Diphtheria	195	8
Laryngeal diphtheria (croup)	5	2
Chicken-pox	30	0
Cerebro-spinal meningitis	0	2
Pertussis	2	0
Parotiditis	1	0

"Children Cry for It."—Mother: "What on earth are you doing to the child, Bridget, to make her cry so?" Bridget (who has just slapped her): "I s'pose it's the medicine, mum; the 'laibul' says as how children cries for it."

Electrolyzed Sea Water as a Disinfectant.—Electrolyzed sea water is a patented germicide made from sea water. It is readily prepared by passing an electrical current of a certain intensity through sea water. The current strength is ten amperes, and the electromotor force four volts. This current is passed through the water for some hours, and by its action sets free the chlorine, which in turn is taken up by the water. The cost of its production is very small, amounting to only a couple of cents a barrel. It is stated to be a fairly good germicide when freshly prepared and when a certain amount of chlorine gas is present; that it is particularly useful for the destruction of the cholera spirillum, but that it is not a good germicide for spores or for the more resisting micro-organisms.

What Can One Believe of Hydrotherapy?—Dr. Charles Ponce de Leon Smith, of Rahway, N. J., attributes his ripe age of one hundred and twenty-one years to his having bathed daily in the Lawrence Brook, and complains because a health board seeks to deprive his sanatorium patients from enjoying the stream's life-giving properties. This is one side of the question. On the other side, we read of the sudden death of an old lady in an institution across the river, after an enforced bath—she having given the authorities full warning of its dangers and having stated to them that she had not bathed in forty years. *Qu'en penser?*

A Medical Poet.—In 1691 the members of the College of Physicians of England were in the custom of giving gratuitous advice to the poor. After a year's experience they found their charity frustrated by the high price charged for physic by the apothecaries. They therefore decided to make up their own prescriptions. Not to be balked of their gains, the apothecaries waged a persistent war. During the time that public feeling was excited, Dr. Garth produced his poem of "The Dispensary." The lines referring to Apothecaries' Hall may be quoted:

> "Nigh where Fleet Ditch descends in sable streams
> To wash the sooty naiads in the Thames,
> There stands a structure on a rising hill,
> Where tyros take their freedom out to kill."

At the accession of George I., Garth was knighted and appointed king's physician in ordinary. His last work was an edition of Ovid's "Metamorphoses." He died on January 18, 1718.

To Improve the Race.—A bill has been introduced into the Ohio legislature to regulate marriages. A physical and mental examination of all who contemplate marriage is advocated in the proposed measure. Strong tendency of the applicants to hereditary insanity, habitual drunkenness, criminal record, tendency toward crime, or a liability to inherit a criminal inclination, imbecility, mental or physical constitutional diseases that might be transmitted to the progeny, consumption, blood diseases, etc., will debar the candidate. If the bill passes it is thought the State will decrease rapidly in population, by reason both of failure to pass the examination and of removal to neighboring States.

Does Suicide Carry off the Unfit?—Not all men who commit suicide ought to do so, and more who do not ought to do so for the good of the race. A selfish man, living as though the whole world was made for his sport or gust, giving free course to every impulse of lust and passion, bringing the natural satiety, disgust, disappointment, and disease on himself of unregulated indulgence, who destroys himself because he has made himself miserable and unfit to live is a benefactor to his race in taking sudden leave of the world, and the world "should speed the parting guest." If the breeding of the unfit to live could be stopped by more frequent suicides of the morally and physically unstable and viciously endowed—the neuropathic cripples, the mentally squint brained and obliquely visioned, the lame and halt and blind in mind and morals, the cataract-covered consciences—the millennium of earthly happiness would begin.—C. H. Hughes, *in Alienist and Neurologist.*

What a Man Eats in a Lifetime.—It is computed, by a contributor of inquiring mind to an English journal, that a healthy man with a good appetite and average drinking-capacity assimilates into his system during seventy years ninety-six and one-half tons of material, solid and liquid; or, putting it in another way, and assuming his weight to be twelve stones, he consumes over twelve hundred and eighty times his own weight of nourishment in the course of a lifetime.

Progress of Science in the Future.—Prof. Ludwig Buchner, in *Appleton's Science Monthly*, after reviewing briefly the scientific progress of the closing century, remarks, in reference to the future outlook: "It may be that we are, in respect to the coming century, in the same immature mental condition in which the people of the eighteenth century were with regard to the nineteenth. If some one in the preceding century had dared to predict the wonderful achievements of the nineteenth, he would probably have been declared a fool, and treated as was Robert Mayer in Germany in this century, who, after the discovery of the law of the conservation of force, was put into an insane asylum. A like fate might befall the man who should dare now to cast a horoscope for the twentieth century and to predict the progress of the human mind in the various domains of scientific research. After all, they may be right who, in spite of all these acquisitions on which we so justly pride ourselves, are of opinion that we are still moving in only the initial steps, in the leading-strings of evolution, and that we are yet very far from the goal of those material and ideal aims which the human race in its unremitting onward struggle is destined to attain or to show its capacity of attaining. The great Sir Isaac Newton used perhaps the most appropriate simile, when he compared men with children who on the seashore are picking up here and there a curious pebble or colored shell, while the great sea of truth lies still unexplored before them. We can only conjecture as to the probable progress, as we cannot know which position we occupy in the course of human evolution, whether we are still in its beginning or well advanced."

Obstacles in the Path of a Doctor in India.—As an illustration of the difficulties with which medical men in India have to contend in their endeavors to stay the plague, the following extract from a private letter received from Bombay may prove of interest: "Often when we pay our visits of inspection to native homes we find the head of the household sharpening a huge knife, wherewith he has pledged his word with neighbors to stab the first doctor sahib who enters his household. In one village we visited, over three thousand of the inhabitants had disappeared and gone to various hiding-places, whence they emerged as soon as we had finished our tour. Of course we were helpless in the matter. We knew the population was missing, but could not scour the country and conduct our physical examinations by force. It would have been like an Afridi expedition. So we returned with our work only half done."—*Hospital.*

Menstruation.—The natural law of which menstruation is a part began when the first leaf fell from the first tree.—Arthur Johnstone.

Asylum Physicians run risks in the daily routine duties that are little known. Dr. Campbell, medical superintendent of the Cumberland and Westmoreland Asylum, writes (*Lancet*, December 18, 1897) as follows: "I have been attacked by a patient with a scythe, who tried to cut my legs through; by a patient with a knife; by a man who waited at the back of a door with a stone in his hand and who smashed my front teeth; and I have had my spectacles smashed on my face—but I still live after thirty-two years spent in an asylum."

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended February 19, 1898:

Small-Pox—United States.

		Cases.	Deaths.
Alabama, Selma	February 14th	2	
Georgia, Atlanta	February 3d to 10th	2	
South Carolina, Charlotte	January 25th to February 12th.	3	
Tennessee, Memphis	February 10th	1	
Texas, Brownsville	January 29th to February 12th.	2	

Small-Pox—Foreign.

Bohemia, Prague	January 22d to 29th	5	
Cuba, Cienfuegos	February 1st to 13th	..	19
Havana	February 3d to 10th	9	
China, Hong Kong	December 25th to January 8th.	5	3
England, Liverpool	January 22d to 29th	2	
India, Madras	December 25th to January 7th.	..	4

BOTTINI'S GALVANO-CAUSTIC RADICAL TREATMENT FOR HYPERTROPHY OF THE PROSTATE.[1]

BY WILLY MEYER, M.D.,

NEW YORK,

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

MR. PRESIDENT AND GENTLEMEN: The surgeon who is called upon to-day to give his advice in regard to the best method of treatment for hypertrophy of the prostate gland still finds himself in a rather embarrassing position. It is true, quite a multitude of operations designed for the radical cure of this trouble are at our disposal, yet to propose the proper one in a given case is doubtless a difficult task.

A great deal has been written on this subject, many discussions have been held concerning the same here and abroad, but we are far from being able to draw definite conclusions as to the value and indications of the various operations.

As the matter presents itself to-day, it seems to me the wiser course, in all cases in which catarrh of the bladder complicates the trouble, not to propose an operation of any kind at once. It cannot be denied that in many instances irrigation of the bladder carried out very carefully by the attending physician under strict aseptic precautions, every day or every other day, yields very gratifying results. This treatment is greatly assisted by the internal application of urotropin, from three to eight times a day, eight grains in capsules or oblates (wafers). Only very recently Mendelsohn, Casper, and others[2] called our attention to the great relief this drug affords patients afflicted with cystitis and pyelitis, also in cases of prostatic enlargement. My personal experience fully corroborates this observation. The favorable influence of the drug is explained by the fact that the urine of persons who have taken urotropin internally frequently contains for many days formaldehyde, the antiseptic value of which is well known. Urotropin is a chemical combination of four molecules of ammonia and six molecules of formaldehyde. Of course, irrigation of the bladder will not generally influence the size of the prostate, and hence not reduce the residual urine, although it has frequently been the means also of improving this objective symptom. But the residual urine as such does not bother the average prostatic patient; what bothers him mostly is the infectious inflammation of the vesical mucous membrane that has been carried into the bladder by instrumentation or by micro-organisms that have wandered from the rectum into that viscus. Frequently the irritability of the bladder is partially caused by a present pyelitis.

If catarrh of the bladder be absent and the case be a recent one that admits of temporizing, we may eventually first try one of the other non-operative methods which have been proposed lately: Rectal tamponade of Manasse, or the parenchymatous injection of cocaine into the testicles with the view to produce atrophy (Coully), although neither of these procedures gives much hope for permanent improvement. The feeding with prostatic tablets might also come into consideration (Englisch, Reinert). The latter author gave a promising report on this branch of organo-therapy before the Thirteenth Congress of German Physicians at Munich, 1897. Of course all these procedures could also be combined with the irrigation treatment mentioned before.

But suppose our efforts to alleviate the patient's condition with these means have not been successful; suppose also that the patient be in the fifties, and refuses to have his testicles removed or his vasa deferentia resected—the two operations which, no matter what great improvements may yet be made in the direct interference for hypertrophy of the prostate, will, it seems, forever hold their place in this branch of operative surgery—shall we then in such a given case resort at once to the more serious operation, namely, that of attacking the gland directly with the help of prostatectomy by the suprapubic or the perineal route, or both routes combined? Or shall we try to influence the size of the organ indirectly by tying the internal iliac arteries—a method which, according to my experience, still deserves a place among the operations for the trouble here under discussion? Or shall we in such cases, when the patient refuses to run the risk involved in either of the afore-mentioned operations, establish a suprapubic fistula with subsequent permanent drainage of the bladder?

With reference to the latter procedure, I will state right here that the oftener I have done it the less I like it. It is true one of my patients, now sixty-seven years of age, has worn a permanent catheter in his suprapubic fistula with comparative comfort since 1888, and still drives to the cemetery—he being a church sexton—several times a week or a month, over rough roads, on a coachman's seat, and empties his bladder every couple of hours through the catheter, which is cut short and closed with a wooden plug. On the other hand, I have seen such patients in a pretty uncomfortable position, and this in spite of my attempts to relieve them with the aid of a more convenient apparatus for permanent suprapubic drainage of the bladder than that heretofore in use—an apparatus which I devised four years ago and after sufficient trial am now ready to publish.

At this time of the still present uncertainty as to how to advise a patient who is afflicted with this most frequent disease, we are greatly indebted to Dr. A. Freudenberg, of Berlin, for urgently having called our

[1] Read at the ninety-second annual meeting of the Medical Society of the State of New York, Albany, January 26, 1898, being part of the discussion: "The Management of Hypertrophy of the Prostate Gland and its Complications." A short abstract of the paper was read also before the section on general surgery of the New York Academy of Medicine, November 8, 1897.

[2] M. Mendelsohn, Berliner klinische Wochenschrift, 1898, No. 3; L. Casper, Deutsche medicinische Wochenschrift, 1897, No. 10, Beilage; J. Cohn, Berliner klinische Wochenschrift, 1897, No. 42; E. Schreiber, Deutsche medicinische Wochenschrift, 1897, No. 11, Beilage. The drug was first introduced and recommended by A. Nicolaier, of Göttingen, as a uric-acid solvent. Lately he also emphasized the beneficial influence of urotropin on infectious processes of the urinary system with ammoniacal reaction of the urine.

attention, in the early part of last year, to Bottini's galvano-caustic radical operation for hypertrophy of the prostate.[1] It is almost incredible that this, as it seems, splendid operation should have been practised for twenty-two years by virtually only one gentleman —namely, the inventor of the method, Enrico Bottini, of Pavia—and that in spite of the fact that he has repeatedly drawn the attention of the profession to his work.[2] A possible explanation I can find only in the fact that the instruments used in this operation were formerly made in Italy, and that Bottini for a number of years never finished improving them. A new impetus to follow in his footsteps was given to the medical profession when the well-known house of W. A. Hirschmann, of Berlin, undertook the manufacture of the instrument, making it a very handy and reliable one.

When Bottini performed his first operation, on October 26, 1875, he made use of the so-called "cauterizzatore prostatico," representing an instrument of the shape of a catheter of medium calibre with a short beak, the latter carrying on a porcelain disc a platinum plate about three-fourths inch long. With this plate, made red hot by the electric current, he cauterized the prostate thoroughly at different spots, if necessary repeatedly. When the eschar had been pushed off, improvement often began to set in; at times it took thirty days before the patients could notice the effect of the interference.

Two years later Bottini was able to publish five successful cases treated in this way.[3] With increasing experience he discarded the cauterisator and made use only of the second instrument, the "incisore prostatico," which removes the mechanical obstruction to the outflow of the urine at the neck of the bladder by slowly burning a groove or grooves through the same and not by superficial destruction. This instrument[4] (Fig. 1) shows a male and female arm, not unlike a lithotrite. The beak of the female part forms almost a right angle with its shank, and has at its concave side a deep groove. The shank of the male arm shows a platinum knife, about five-eighths inch long (*Pl. kn.*), which leaves the groove of the female arm on turning an Archimedean screw (*Ar. Scr.*) at the outer end of the instrument. A scale (*sc.*) attached to the latter admits of exactly gauging the length of the groove to be cut. The instrument further shows the so-called cooling apparatus which was added to it by Bottini in 1882, and which, no doubt, constitutes a very important feature, inasmuch as this alone saves urethra, prostate, and bladder from accidental burns. A short metal tube, the outflow of which is covered by rubber tubing (thick walled, to prevent bending), enters immediately below the lower end of the handle, and runs through the entire length of the shank and through the beak to the opposite side of the instrument, there showing an outlet of the same shape and length. Over this another rubber tube is slipped. The nozzle of an irrigator filled with cold water is attached to one end of the tube, and when the water is turned on the mechanism performs its function so exactly that the finger can touch the beak or the shank at any spot without the slightest sensation of heat, although the platinum knife has been made red or even white hot.

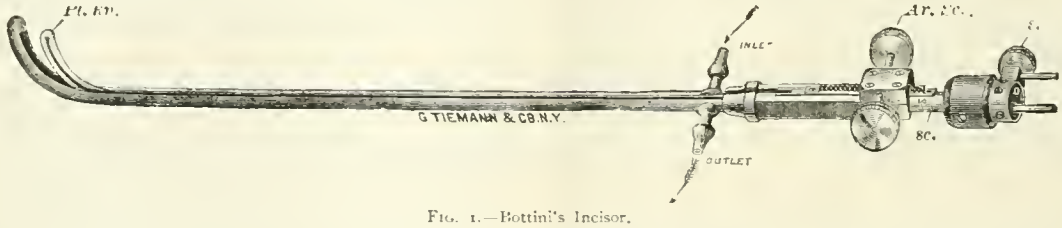

Fig. 1.—Bottini's Incisor.

In working with this instrument a number of drawbacks were observed. Thus it happened that the platinum knife, when heated and slowly ploughing its way through the prostate, being pulled or pushed by the turns of the Archimedean screw, bent sideways; on its return it then did not slip into and disappear within the groove of the female shank. The reason for this annoying accident was first thought to be insufficient heating of the knife, owing to too weak an electric current, and certainly this factor must be considered. But later it was found oftener in the fact that the well-heated knife became crooked on account of a turning sideways of the entire instrument in the hands of the operating surgeon. This happened so easily on account of the absence of a proper handle. The result of such an accident is that the removal of the instrument from the bladder and urethra is difficult, causes pain and hemorrhage (Czerny). Furthermore, the cooling apparatus, entering the shank below the incommodious handle, did not prevent the latter from becoming heated by the current. The conductors were eccentrically attached to the upper end of the instrument; when the latter was turned around its longitudinal axis, they became twisted. The instrument on the whole was too light and too long.

A. Freudenberg, of Berlin, who found these drawbacks by practical use, has greatly improved Bottini's instrument with regard to its shape and handiness, as well as to its electro-technic construction and possibility of sterilization (Fig. 2). He somewhat shortened that part of the instrument which enters the urethra and bladder (shank twenty-six centimetres instead of twenty-seven centimetres), at the same time making it considerably heavier by providing it with a compact handle (*Gr.*), seven centimetres long, such as we are used to grasp when working with the lithotrite. He moved the small water pipes of the cooling apparatus (*K*) to the upper end of the handle, and gave them an obliquely downward and inward direction.[1] At this place the rubber tubes will not be compressed so easily by the operator's hand; but they must nevertheless have a sufficiently thick wall not to bend when the instrument is turned. The cold water, running also through the handle, keeps the latter always cool. The two cables are thinner than those in the original Bottini incisor, and, with the help of a silk texture woven around them, are united into one big cable (*L*). The latter, being attached to the cable contact (*P*), can be easily slipped over a pivot at the upper end of the longitudinal axis of the instrument (*C*). This point moves up and down with the turning of the wheel, and carries both poles in a concentric arrangement. One push on the cable contact suffices to unite the parts. A small contact screw (*CS*) makes and breaks the current. This screw is also found in the

Archiv für klinische Chirurgie, vol. xxi., 1877, pp. 1–24, and vol. liv., 1897, Heft i.; previously published in the Italian language in La Clinica Chirurgica, July 31, 1896, tome vii., p. 281.

[3] Archiv für klinische Chirurgie, xxi., 1877, *loc. cit.*

[4] The instrument was first demonstrated by me before the surgical section of the New York Academy of Medicine, November 8, 1897.

[1] The position of these two tubes will always tell us to which side the beak of the instrument is directed, after the latter has been introduced into the bladder. They correspond to the concave side of the beak.

original Bottini instrument (Fig. 1, *s.*). The scale marks (*Sc.*), on the central stem just below the wheel —which latter, by being turned, moves the platinum knife up and down—are made all around the stem and show numbers at every 120°, *i.e.*, three times. This enables us always to satisfy ourselves as to the distance between the knife and its groove, no matter how we may have turned the instrument. In the original Bottini these marks are engraved on one part of the circle only. The principal improvement, however, is found in the platinum knife (*Pl*). As stated above, that in Bottini's incisor sometimes bends sideways and then does not enter the groove of the female shank. To avoid this as much as possible, the groove itself has been widened; the knife is made of an alloy of platinum with iridium, which is much harder than the pure platinum and offers greater resistance to the electric current. For that reason a weaker current suffices to heat it. With this same point in view—namely, to reduce the demands on the battery—the electric conduits were changed. Instead of running two very small wires down to the platinum knife through the shank of the male part, one single wire of double calibre has been substituted. It corresponds to the positive pole. The negative pole is directly united with the metal of the male shank, and, on account of the close contact of the latter with the female one, virtually with all the metal of the instrument. In this way it was necessary to connect but one end of the knife with the wire; the other one could be directly soldered to a projection of the metal at the lower aspect of the male shank. As will be readily seen, the position of the knife is thus made much firmer than it is in Bottini's incisor, in which it is attached to two wires. By selecting for the occlusion of the male shank a cement which can be thoroughly exposed to water and heat without being affected thereby, it could be arranged to sterilize the entire instrument by boiling, the same as we are wont to do with other surgical implements.

I am sure Bottini's incisor, as modified by Freudenberg, is the one which will be used by surgeons when dividing the hypertrophied prostate with the galvanocaustic knife introduced through the urethra. It is manufactured in the Electro-Technic Institute of R. Kiss, Berlin, Königgrätzer Strasse 85. It impresses one as being a very reliable instrument.[1] It is worth stating that Bottini, at the last international medical congress, at Moscow, gave preference to this improved instrument.

The operation itself should, if possible, be preceded by a cystoscopic examination, a point which has been emphasized already by Freudenberg. This will enable us to avoid any difficulty during the after-treatment which may be caused, for instance, by the presence of a vesical calculus which has not or could not have been detected with the searcher. It will also inform us regarding the configuration of the prostate, as to the presence of a median lobe, and as to any difference in the size of the lateral lobes, which latter fact may also be corroborated by outlining the internal contours of the prostate with the stone searcher; it is often supplemented by rectal digital examination.

I want to emphasize here the fact that we can very well diagnose the configuration of the prostate with the help of the cystoscope, partly by observing the shape of the internal vesical fold, partly by bringing the handle of the cystoscope over to one side of the patient, thus conducting its beak into the bladder as far to the one side as possible. In this way we can often clearly distinguish a swollen median lobe, which then, however, is generally not brilliantly illuminated, but rather lies in the shade. I state this particularly to contradict Dr. E. Fuller, who maintained, at one of the late meetings of the section on genito-urinary surgery of the academy, that this was an impossibility and mainly existed in the phantasy of the observer. To prove the correctness of my statement, I would mention the case of the father of a colleague, on whom I was requested, some seven years ago, to perform cystoscopy for hypertrophy of the prostate. In this case I distinctly diagnosed a median lobe of the prostate projecting into the bladder, almost as long as the third phalanx of the little finger; there was besides general hypertrophy of the gland. This patient was later operated upon by Dr. Edward L. Keyes, by suprapubic radical extirpation of the gland, when the condition of the prostate was found to be exactly as previously seen by me through the cystoscope.[1]

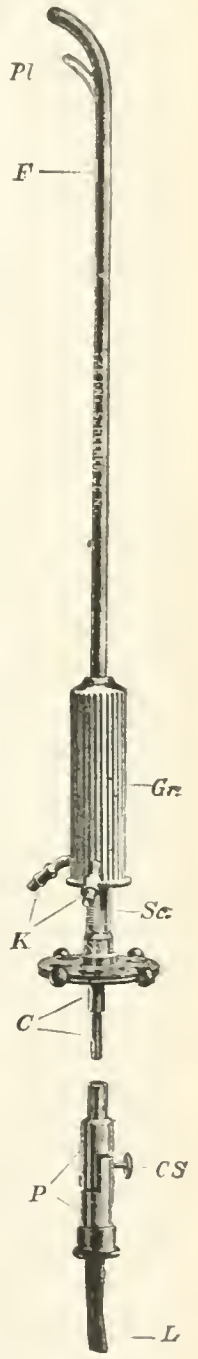

Fig. 2.—Freudenberg's Modification of Bottini's Incisor.

The technique of Bottini's operation is simple. After the bladder has been carefully irrigated and emptied, the posterior urethra is locally anæsthetized with cocaine or eucaine, one and one-half drachms of a one or two per cent. solution (eucaine, five per cent.) being injected either into the posterior urethra directly or into the anterior portion of the canal, and then pressed backward by gentle massage over the perineum. Five minutes later the mucous surface will be found to be sufficiently insensible to render the operation painless.[2]

Before the incisor is introduced pains must be taken that the bladder is thoroughly emptied, for it is obvious that then the effect of the cautery is far stronger. It is also necessary to test the efficiency of the battery repeatedly before starting the real work. With the help of the rheostat attached to the battery, the electricity needed for heating the instrument is gauged so as to allow the platinum knife to turn thoroughly red hot. If this is carefully attended to, no bleeding will set in after the operation. In order to ascertain how well the heated knife will cut its way through the prostatic tissue, Bottini advises taking a piece of moist sterile gauze and trying the knife on that first.[3] It is, furthermore, necessary that an assistant be ordered to do nothing else but watch the work of the cooling apparatus. He has to see to it that the outflow of water from the instrument never ceases.

[1] The instruments, Bottini's and Freudenberg's, were imported for me by the Kny-Scheerer Company, 17 Park Place, New York City. Both are now manufactured in this country by this company; Bottini's original instrument also by Messrs. George Tiemann & Co. Freudenberg's instrument was demonstrated by me before the section on genito-urinary surgery of the Academy of Medicine, December 14, 1897.

[1] New York Medical Record, 1891, vol. xl., p. 526, Case II.

[2] Bottini succeeded in doing the operation even without cocaine, and heard his patient complain of a momentary pain only when opening and closing the electric current. If patients suffer from painful spasmodic contractions of the detrusor muscle, when the bladder has been entirely emptied, it seems to me wiser to put them for the brief operation under the influence of general anæsthesia (Schleich's solution No. 1).

[3] I deem this point to be very important.

These preliminaries having been carefully observed, and the screw at the outer end of the instrument (*CS*, Fig. 2), which makes and breaks the current, having been turned to the left, thus temporarily breaking the current, the instrument is introduced into the bladder in accordance with the rules of ordinary catheterism.

Whoever has seen a case of marked hypertrophy of the prostate when the bladder was opened by suprapubic incision will have found that the gland in a great many cases surrounds the internal urethral orifice in the shape of a collar. With other words, there is a circular swelling at this spot, which, of course, is most pronounced in its lower half. On the basis of this anatomical fact, Bottini burns with his incisor one, two, or, better still, three grooves at one sitting—namely, a short one toward the symphysis, another just opposite directly backward toward the rectum, and a third one through that lateral lobe of the prostate which appears to be the larger one. Following his advice, we shall therefore, in a case of very marked hypertrophy of the prostate, as soon as the instrument has entered the bladder, pull it forward toward the anterior wall of the bladder, at the same time slightly raising the handle outside, until we feel the resistance inside. Then the cooling apparatus is started and the screw at the outer end of the instrument turned to the right, thus making the current. We wait about fifteen seconds until the platinum knife gets red, and then slowly turn the Archimedean screw to the left on Bottini's original instrument, or turn the wheel to the right on Freudenberg's modification, reading on the scale how far we have proceeded. If the knife does not work easily, the current is slightly increased; if it cuts too easily, the current is reduced. After a groove of the contemplated length has been burned, the knife is made to return to the groove of the female shank by turning the screw (wheel) to the opposite side. It is wise, according to Bottini, slightly to increase the current for this procedure. Now the current is broken, and the beak of the instrument turned downward and pulled gently forward, so as to hug the prostate. Then, according to necessity, one or two more grooves are made through the body of the prostate in the same way as just described.[1] If during the operation an assistant auscultates the suprapubic region, he will distinctly hear the noise which is produced by the burning. Sometimes this can be heard even by bringing the ear near the abdomen. The two or three grooves thus having been cut, the current is turned off and the instrument gently extracted from the bladder. The operation is finished. According to the number and length of the grooves cut, it lasts from two to five minutes. The inconvenience caused the patient during and after the operation is exceedingly slight. A physician operated upon by Bottini without cocaine pronounced the procedure less painful than the instillation of nitrate of silver into the prostatic urethra. Two of Freudenberg's patients stated that the operation had caused them less pain than the preceding cystoscopy. Another said that he preferred it to the examination with the stone searcher.

Soon after the operation most of the patients complain of a burning sensation when commencing to pass water. They may get up right after the operation in order to urinate, and can be permitted to be permanently out of bed on the second day, the general reaction of the operation being in most instances almost *nil*. If the bladder has been carefully irrigated, the patients will rarely develop any rise of temperature; bleeding, if there be any at all, is generally of minimal amount. The urine passed during the first night following the operation is often macroscopically free from blood. In more than eighty cases of this kind, Bottini has not seen a single serious hemorrhage. For this reason he warns against the use of a permanent catheter. Thus the after-treatment is comparatively very simple. If necessary, the bladder should be washed out daily in order to improve the present cystitis — best with a cold solution, as this will strengthen the contractility of the detrusor muscle. This latter may also be accomplished with the help of electricity. Strychnine internally is advisable. It is a matter of course that the detrusor muscle regains its full power of contractility only in course of time.

As regards annoying accidents during or after operation, Czerny once had a bend in the platinum knife which made the extraction of the instrument slightly difficult. This occurrence has been referred to above.

Kümmel, who has operated with the help of the cauterizator in a number of cases of urinary retention, once saw a rather serious hemorrhage on account of the patient having removed the permanent catheter which had been introduced. In order to stop the hemorrhage he then performed suprapubic cystotomy. The patient died a few days later. (As just stated, Bottini warns against the use of a permanent catheter.)

As Bottini maintains, Czerny as well as Kümmel made use of inferior batteries, which not only are unreliable in their effect but do not heat the knife sufficiently. Freudenberg explains Czerny's experience as being caused by turning the instrument (Bottini's original) when the heated platinum knife is doing its work (see above). It certainly is of greatest importance that a sufficiently powerful and absolutely reliable battery with a rheostat attached be used. As far as I have seen, the storage batteries for sale here do not well answer this purpose; they are not made to bring to red heat so large and thick a platinum knife as the one needed in this operation.[1] At present I use a battery manufactured by Hirschmann, of Berlin. It is, however, so heavy as to require two men to carry it. Freudenberg recommends a battery with an ampere meter, made, according to his design, by Kiss, of Berlin. This is the same concern that has brought the improved incisor upon the market. The ampere meter enables one to know at every moment the exact strength of the current, and thus the degree of heat attained by the knife. I have just brought out a useful small storage battery for Bottini's operation, with the kind assistance of the Kny-Scheerer Company, 17 Park Place, New York City. It is not heavy and can be easily transported.

L. Casper, of Berlin, when discussing[2] Freudenberg's last paper on this subject, "Zur Bottini'schen Operation bei Prostatahypertrophie,"[3] stated that the dangers connected with this procedure were hemorrhage, dribbling, and infection.

Freudenberg saw a secondary hemorrhage in three of his cases. In one of these the bleeding ceased after a permanent catheter had been put in for three days. Here the occurrence was later explained by the discharge of a piece of the prostate, of the shape and size of a split almond. This portion had been cut off from the right lateral lobe, which projected into the bladder—an accident which had never been observed before. In his other two cases the hemorrhage was not at all alarming. In watching these patients after the operation, one ought to be mindful of the fact that hæmaturia generally makes a more serious impression than is warranted by the amount of blood actually lost. Freudenberg believes that the danger of hemorrhage

[1] In my last two operations I have primarily divided the body of the prostate in its median and lateral lobes and then added a short anterior incision. The posterior (sagittal) incision, down to the floor of the bladder, is certainly the most important one.

[1] A friend of mine has informed me recently that the Edison-Laland Company is making a battery which would probably do good work.

[3] Read before the Berlin Medical Society, October 20, 1897; Berliner klinische Wochenschrift, 1897, No. 46, p. 1,002.

greatly depends upon the operator. This is certainly true. It is self-understood that Bottini's operation, small and easy as it may appear at the first glance, also has its technique. And this technique in all its details must be mastered by practical experience. The result of the operation largely depends upon the proper observation and carrying out of quite a number of details. The length, direction, and number of cuts, the rapidity with which they are made, the amount of current used for heating the knife—all deserve to be mentioned in this connection.

Freudenberg also saw dribbling in a few cases after operation, but in no instance was it marked or did it become permanent.

This observation corresponds with the experience of Bottini, who informed Freudenberg, upon the latter's query, that he never saw enuresis as a result of his operations. Freudenberg, on the other hand, observed enuresis to disappear in three cases when it had been present before the operation. With reference to avoiding this occurrence, he also emphasized the necessity of sufficient practical experience. He believes that enuresis will probably set in if the grooves are burnt through the prostate into the membranous urethra or very close to the latter.

The danger of infection, as far as it might be carried into the bladder by the operation itself, has been eliminated since Freudenberg has completed his improved incisor, which can be sterilized by boiling.

As is natural, a number of objections against Bottini's operation have been raised in the course of time. Webb,[1] McGill,[2] and others stated that the operation was dangerous. However, Bottini has had but two deaths in a series of more than eighty cases—certainly a minimal death rate for an operation which is almost exclusively performed on old and decrepit patients; and these two deaths occurred before the cooling device had been added to the cauterizator.

Freudenberg lost two patients: one died from embolism into the lungs—an exceptional experience after Bottini's operation so far: the other, a very weak and much-reduced patient, seventy-seven and one-half years of age, died twenty-four days after—better, in spite of the operation.

McGill further believes that the operation could prove of benefit in but exceptional cases, because the real condition of the prostate could be properly made out only with the finger in the bladder or by direct inspection. Nitze's cystoscope refuted this objection as soon as it was raised.

Nitze[3] believed that the separated parts of the prostate would grow together again and thus cause a recurrence of the trouble. But, as Freudenberg insists, the act of micturition alone, which each time presses apart the walls of the grooves, renders reunion of the divided parts impossible. The same effect is probably produced by the tonus of the external sphincter muscle, the central fibres of which are divided by the operation. In the main, however, practical experience has proven the contrary of Nitze's objection. Bottini, who by his writings impresses one as being a very careful, straightforward, and upright observer, has never seen a recurrence of the trouble during twenty-two years of actual practical experience.

In perusing the literature of Bottini's operation, I find that so far only a few authors have tried this method besides Bottini, who, as stated before, has operated in more than eighty cases. Up to 1890 Bruce Clark was the only one who reported a successful case. He made use of the cauterizator. When discussing Bottini's paper, read before the Tenth International Medical Congress, at Berlin, in 1890, Clark stated[4] that this patient was still alive, could urinate without difficulty, and had gotten rid of his catheter. Without giving further details, he added that he never since had a similar result. How many cases this "never since" comprises remains doubtful. He certainly did not make use of a sufficiently strong current, for he himself says that "the current which I employed was a much weaker one" (than that of Bottini).

H. Kümmel, of Hamburg,[5] has operated with the cauterizator on a number of patients with hypertrophy of the prostate and retention, and is well satisfied with his results.

V. Czerny, of Heidelberg, has used the incisor five or six times,[6] and, although he had a very inferior battery, has never noticed an ill result, but in the majority of cases a marked improvement—spontaneous micturizion, or at least easier introduction of the catheter. He remarked last year that Bottini's operation deserves more attention than it has hitherto received.

Watson[7] states that he has had some experience with Bottini's method. He wants it reserved for cases with a hypertrophied median lobe.

L. Casper[8] has done the operation seven times on six patients—twice with satisfaction, three times with quite a good result, the sixth case being of too recent date to admit of drawing conclusions. He feels so much encouraged that he will continue to use the method.

Next to Bottini, Freudenberg has had the most extensive experience. He at first published five cases in which he operated with Bottini's incisor.[9] Of three of his patients who had suffered for months with complete urinary retention, one—who was operated upon twice, six days intervening—commenced to pass his water on the tenth and fourth days respectively after the operation; the two others began to void their urine spontaneously three and four hours after the operation. In a second group, comprising two patients who still were able to pass water, but had to urinate every twenty or thirty minutes with a great deal of pain if they did not catheterize themselves, the operation had a very favorable result with regard to the frequency of micturition. All of the five patients have gotten rid of the catheter; all have materially gained in weight and improved in general health; two of them—one a patient of eighty-one, the other sixty-seven years of age—who were in a deplorable condition before the operation, were evidently saved by the interference.

When demonstrating his last patient thus operated upon, before the Berlin Medical Society, October 20, 1897, Freudenberg mentioned that he had performed Bottini's operation eighteen times on fifteen patients; that he had always used the incisor, and three times his modification of the original instrument, to his greatest satisfaction. The case then presented is of such importance that I will here briefly append the history:

The patient, sixty-three years of age, had been a slave to the catheter on account of complete urinary retention for the last three years and a half. On June 5, 1894, both his testicles had been removed by Casper, of Berlin. The retention remained unimproved. Three years later the patient still had to catheterize himself four or five times in twenty-four hours. In spite of regular, careful irrigation of the bladder, some vesical catarrh was always present. The prostate was

very soft and bulged into the rectum; the upper end could not be reached with the finger. On April 22, 1897, almost three years after castration, Freudenberg performed Bottini's galvano-caustic radical operation on this patient. He burnt three grooves—one directly backward, three centimetres long; one of the same length through the left lateral lobe; and one, two centimetres long, anteriorly. Five and one-half hours after this operation the patient commenced to void his urine spontaneously; ten or twelve days later he voluntarily emptied his bladder almost completely, and after May 31st, or thirty-four days after the operation, the catheter was not used any more. Six months later the patient urinated in a good stream without any difficulty six or eight times in twenty-four hours, including once during the night. The urine had become perfectly clear. This improvement of the affection of the bladder had taken place without the use of strychnine, electricity, or cold intravesical douches. The patient had taken salol and urotropin internally. He had also lost his former constipation — an observation made by Freudenberg a number of times in patients on whom he had done Bottini's operation. The patient had gained seven pounds, although he had been quite stout before. He enjoyed life and regretted the loss of his testicles.

Bottini reported [1] a similar case, in which vasectomy had been done before, also without improving the bladder function. His operation cured the patient.

These cases speak for themselves. They prove beyond a doubt that the effect of Bottini's operation means the successful overcoming of the mechanical obstruction offered to the outflow of urine by the hypertrophied prostate. They also refute Lenander's (Upsala) explanation as to the effect of Bottini's operation,[2] viz., that the cautery knife burns the caput gallinaginis and thereby destroys the ejaculatory ducts, also the ganglia and nerves which run to the seminal vesicles and the vasa deferentia; with other words, that Bottini's operation means about the same as the resection of the vas deferens.

My personal experience so far is very limited. I have operated three times on two patients; once with Bottini's and twice with Freudenberg's improved incisor (at time of publication, four times on three patients, three times with Freudenberg's instrument). Both men were still able to pass water, but urinated, always with a great deal of pain, every twenty or thirty minutes day and night. Both had unilateral or bilateral pyelitis and purulent catarrh of the bladder; their prostates were very soft; they had been treated by a number of doctors before.

In the first patient, fifty-eight years old, I have done the operation twice at the German Hospital, on October 7[3] and December 18, 1897. (The long interval was due to the delay in the arrival of a suitable battery from abroad.) The patient had, as made out by rectal palpation, a very small prostate—so small that one might have with propriety made the diagnosis of "prostatisme vésicale" (Guyon). But the gentle exploration of the interior of the bladder with the stone searcher demonstrated an enlarged gland, and the cystoscope showed the prostate bulging into the bladder and the internal urethral fold irregularly curved; there was no median lobe. All clinical symptoms generally found in prostatics were well defined. Voluntary urination, 25 c.c.; residual urine, 300 c.c. When the bladder was emptied he had excruciating pain. For this reason I put him under general anæsthesia for both operations (Schleich's solution No. 1). I satisfied myself that the interference is a simple one for the doctor who is used to doing intravesical instrumentation. I was astonished to note how easily the prostatic tissue could be penetrated; it appeared to be extremely soft in this case. Although I had carefully gauged the heating of the knife before introducing the instrument, and although my assistants on auscultating the suprapubic region were sure to hear the noise of the cautery, I am under the impression that at the first operation, October 7th, I had not heated the platinum knife sufficiently (I had omitted to test the heated knife first on a piece of moist aseptic gauze), and that I cut the grooves too fast (a great deal of unburnt prostatic tissue adhered to the knife when the instrument was removed). At that time my storage battery was an unsatisfactory one. The operation itself (three grooves, 2.5, 2.5, and 1 cm., were cut) had lasted scarcely five minutes; there were no ill after-effects. The patient was up and about the next day. At his request he was soon discharged. Six weeks later he urinated just as often as before the operation, but without any pain. Ten weeks after the operation he passed water not quite so often as before during the day; at nights, only three or four times. The amount of residual urine was unchanged (15 : 280 c.c.). My proposition, which I had also made before the operation—namely, to draw off the residual urine—was again refused on account of the pain that set in when the bladder was emptied. On December 18, 1897, a second operation was performed with Freudenberg's modified incisor and a storage battery from Berlin. The patient again stood the operation well, and was up on the following day. Being opposed to subsequent local treatment, he left the hospital a few days later.

On February 16, 1898, I saw him at my office for the first time after the operation, and was greatly pleased to get from him the following report: A few days after the operation partial incontinence (dribbling) set in, more pronounced during sleep. This lasted two weeks. From that time on improvement has been gradual and continuous. To-day the patient does not experience any pain whatsoever; urinates three or four times during the day, twice during the night; amount each time about six or seven ounces, which is passed in the course of three or four minutes. For three weeks past he has been at work in his former occupation; he has gained in weight. When at my office he declared he had no desire to urinate, but I made him do so, nevertheless. He passed 20 c.c. (residual urine, 180 c.c.). The patient pronounced the small quantity passed an exceptional occurrence. Certainly we have a right to call his condition to-day much improved.

The amelioration of the different symptoms in this case is entirely due to Bottini's operation, because the patient did not undergo any after-treatment whatsoever. The few vesical irrigations carried out at the hospital after the operations, also during November at my office, made him decidedly worse. I must confess I had not expected so gratifying a result in this case, and therefore also feel very hopeful as to the future of this method of operation. The urine at present is acid, but very turbid. I have urged the patient now to undergo local treatment. I shall not fail to report on the progress of this case after some time.

My second patient, a man of seventy-three, was in a deplorable condition when he came under my care. Residual urine, 10 : 160 c.c. Prostate not large and very soft on rectal palpation, upper border could be reached; but found with the searcher to be considerably hypertrophied. Cystoscopy: Markedly trabecular bladder; diverticulum in right part of fundus; no stone; no enlarged median lobe; body of gland distinctly bulging inward. December 23, 1897, after preliminary careful irrigation, three cuts under cocaine—

[2] Centralblatt für Chirurgie, 1897, No. 22.

[3] This seems to have been the first Bottini operation on this side of the ocean. I did not find a single case previously reported in American medical literature.

posteriorly and to the right, 3 cm.; anteriorly, 1.5 cm. No subsequent hemorrhage, no fever; patient up on the following day. Until January 8th, there was no improvement; the patient then entered another hospital. Meanwhile he has died, without having been benefited by the operation.

Since reading this paper at Albany, I have done Bottini's operation on a third patient, sixty-four years of age, who had suffered from increased frequency of micturition and repeated hæmaturia; also from catarrh of the bladder and bilateral pyelitis during the last two years. The patient died thirty hours after the operation, with very high temperature and a failing heart (acute sepsis [?]). I deem the case of great importance, and will therefore here append its history. The patient was first seen by me on December 13, 1897. He then stated that one year ago, when in the northern part of the State, he contracted a cold and for the first time passed blood on urinating. He was brought to a nearby city, where he was put to bed and treated by a doctor. He soon returned to his home in New York. During the hot summer months hæmaturia returned twice. After the last attack a doctor introduced a searcher into the bladder. The answer was bilateral epididymitis. On examination I found the patient to be greatly reduced, pale, and nervous; the epididymis on either side was much enlarged and painful. One hundred and fifty cubic centimetres of urine was passed voluntarily; residual urine, 450 c.c. The urine was turbid, contained one-fourth per cent. of albumin, no sugar, a considerable amount of pus, a moderate amount of mucus, hyaline casts, and cells of all layers of the bladder, also groups from the renal pelvis. The daily excretion of urea and chlorides was not quite up to the normal. The prostate was soft, large, bulging into the rectum; its upper end could not be reached with the finger. The region of both kidneys proved sensitive on pressure. The patient's stomach was constantly upset; he had not taken any solid food for some weeks, and had had frequent vomiting. Cystoscopy (December 20, 1897) was very difficult, on account of hemorrhage; Nitze's irrigating cystoscope was used. I got only one good glance at the interior of the bladder, and saw a very pronounced trabecular condition; no stone; median lobe (?).

During the subsequent weeks I washed out the bladder very carefully under aseptic precautions, every second or third day at my office, and put the patient on increasing doses of urotropin. The condition of his bladder improved, but of course not that of his kidneys. I frequently noticed that, when leaving the catheter *in situ* after careful flushing of the vesical viscus, a few drops of turbid urine would soon run out suddenly, although the irrigating fluid had before repeatedly returned perfectly clear. The clinical diagnosis of unilateral, perhaps bilateral pyelitis was established beyond a doubt. The improvement of the vesical catarrh, however, did not materially improve the patient's general condition. He continued to urinate every thirty to ninety minutes day and night; the residual urine did not diminish. His stomach remained very irritable; he had absolute aversion against solid food. He lost continually in weight, despite the most tender nursing by his devoted wife. Something had to be done. After careful deliberation I resolved to do Bottini's operation. It was performed at the patient's home, on January 29, 1898. All instruments to be used were carefully sterilized according to standard rules, as was also Freudenberg's modification of Bottini's incisor, which, as mentioned above, can well be boiled; my own and the assistant's hands were disinfected in the same way as in other operations. After irrigation of the anterior urethra the urine was withdrawn from the bladder, and the posterior urethra and bladder were repeatedly washed out with a two-per-cent. sterile boric solution. During the latter part of this procedure the patient was brought under the influence of Schleich's solution No. 1. Also in this case I thought it best to use general anæsthesia, on account of the painful, spasmodic contractions of the emptied bladder. At the same time I gauged the amount of current needed to make the knife red hot, tried its efficient working on a piece of moist sterile gauze, and properly arranged the irrigation through the cooling apparatus, which latter matter was in the hands of a trustworthy assistant. As soon as the irrigating water returned entirely clear and the bladder was emptied, the catheter was withdrawn. Next, Freudenberg's incisor was lubricated with glycerin and introduced. As I had raised the patient's hips on a hard pillow, thus putting him in a slightly recumbent posture,[1] it was not difficult to make the instrument enter the bladder, although the latter was entirely empty. Three grooves were cut—one posteriorly in the median line, 3.5 cm. long; another through the right lateral lobe, of the same length; and a third one, 1.5 cm. long, toward the front. Then the instrument was withdrawn and the patient brought to bed. The whole procedure had lasted not longer than five or six minutes. The operation was completed at 4 P.M. The patient was awake about five minutes later. There was a little bleeding from the urethra. It came from the external meatus, which was rather narrow. The same had been noted when I had performed cystoscopy on this patient. A nurse was put at his side.

Ten hours after the operation, at 2 A.M., January 30th, I received a report from the nurse that the patient, at 1 A.M., had had a severe chill, lasting about thirty-five minutes; that the temperature, which previously had been 99° F., had risen to 103.8° F.; and that the pulse, which had been 80 before, was 122. At 11 P.M., seven hours after the operation, he had urinated about three ounces, slightly tinged with blood, in the recumbent posture—a procedure which had not been possible within the last year. Since the chill he had been rather restless, but had very little pain; after a while he seemed to become delirious.

When I arrived at the patient's home, at 2:45 A.M., I found a colleague at his bedside, who reported that he had been obliged to administer one-fourth grain of morphine, on account of the sudden wildly delirious condition of the patient, who now rested on his back quietly in profound sleep. I at once made the necessary preparations for an aseptic catheterization and irrigation of the bladder. I withdrew 350 c.c. of a slightly sanguinolent urine of alkaline odor. Upon irrigation the fluid soon returned absolutely clear. I was satisfied that there was no hemorrhage coming from the prostate gland. At 3:30 A.M. the patient's temperature was 106.8° F.; pulse, 140. We then at once started with hypodermic stimulation and rectal injections of hot saline solution with whiskey. Later in the day we added continued rectal irrigation (Kemp) with saline solution of 105° F., to which was added salicylate of sodium, so as to make a one-per-cent. solution of the same. On catheterization at 12 M. the bladder was found to contain only half an ounce of urine. There was no hemorrhage. But, in spite of all efforts, the temperature did not come down nor did the heart respond to stimulation. The patient died at 10 P.M., without having regained consciousness.

To my regret, permission for a post-mortem examination could not be obtained.

In reviewing this case I cannot make any other diagnosis of the immediate cause of death than that of

[1] Such a posture is of great value. It facilitates the introduction of the instrument into the empty viscus; the region of the prostate being more elevated than the fundus of the bladder, the small amount of urine which will descend from the kidneys, during the short operation, will run into the fundus; thus the field of operation is kept dry.

foudroyant sepsis, although the patient had a moist tongue until his death. And this sepsis had occurred in spite of the most careful aseptic work before, during, and after the operation.

The other diagnosis which might come into consideration as the immediate cause of death is embolism of the lungs, which, as stated above, has been observed in another case subjected to Bottini's operation by Freudenberg. However, a very able medical man, who saw the patient with me, on auscultation could not find any symptoms that would justify such an assumption. There were also missing the rapid respiration, the cough, etc.

Certainly this case gives a great deal to think about. Two questions principally present themselves for discussion:

1. Was it correct to perform Bottini's operation on this patient at once? Would it not perhaps have been better first to have insisted upon resection of the vasa deferentia or of the principal vessels and nerves of the spermatic cord (Albarran's angio-neurectomy), especially in view of the bilateral chronic epididymitis, before resorting to a direct interference with the gland?

2. If the patient really died of acute sepsis, where had been the point of entrance of the streptococci?

With reference to the first of the two questions, future experience must decide whether we are justified in always giving Bottini's operation the first place when trying to bring radical relief to a patient suffering from hypertrophied prostate and its sequela. At present I do not believe that Bottini's operation, as Freudenberg seems inclined to think, should always be our first choice. Perhaps more extended experience may show it to be more advisable in all cases when pyelitis is surely present, when the prostate is soft and easily bleeding, when the patient's condition is run down and the urethra and bladder are not used to frequent instrumentation,[1] first to resect the vasa deferentia (or do Albarran's operation), and await the result of this operation, provided waiting is permissible, and then, if necesssary, add Bottini's operation.

According to present views the effect of the several operations mentioned, as also of castration, is to be found in a depletion of the enlarged, intimately connected, venous plexuses of the prostate, of the neck and of the wall of the bladder. And this depletion is due[2] to direct or to reflex irritation of vasomotor sympathetic fibres that were affected by the operation and now produce a contraction of the vascular walls. We can more or less rely upon this result of the operation. If, after this much has been achieved, the patient should still be unable to pass urine voluntarily or in a sufficient quantity, the galvano-caustic division of the prostate, as stated above, should be added instead of castration. The patient will then have more assurance that he will not succumb to an embolism of the lungs —one of the two principal dangers, as it seems, of Bottini's operation. It is reasonable to believe that such embolism is to be traced to the thrombi made by the galvano-caustic knife in the large veins of the prostatic plexus. Although so far this occurrence has been observed and proved by post-mortem examination but once (Freudenberg), we must admit the possibility of a repetition. The patient will, furthermore, not be deprived of having intercourse or be exposed to the possible consequences of castration (mental disturbance, etc.).[3]

[1] I specially emphasize these points. The remarks following refer to such patients only.

[2] Hoffmann: "Beiträge zur operativen Behandlung der Prostatahypertrophie," Beiträge zur klinischen Chirurgie, Band xix., Heft 3, p. 541.

[3] In view of the rather doubtful permanent results of vasectomy (cf. Hoffmann, *l. c.*), it seems to me to be a good plan to do Bottini's operation in every one of these cases, one to two weeks after vasectomy.

Question No. 2: Where has been the point of entrance for the streptococci in the case just related? Can we avoid at all, and, if so, how can we avoid sepsis, the second danger, in my opinion, connected with Bottini's operation?

It is evident that a trabecular bladder of a prostatic cannot be properly disinfected by continued irrigation. It is obvious that vesical irrigation does not influence the renal pelvis. The latter can be prepared for the operation by internal medication only—urotropin and salol. The fear, therefore, that a wound made within a bladder that cannot be reliably disinfected and remains a closed viscus after the operation—a viscus that is not drained as we are used to do after suprapubic or perineal incision—I say, the fear that such a wound may be the direct cause of infection to the patient must certainly be entertained. I believe that this danger does exist, although to but a limited extent. The eschar produced by the red-hot Bottini knife will generally be very slowly pushed off, certainly not before the fourth or fifth day, and this pushing off is caused by the reaction of the surrounding living tissues, namely, granulation. We all know that, if not irritated, such a granulating surface forms the best barrier against infection, and not the entrance for infectious micro-organisms.

But it should not be forgotten that a thrombus is formed in the prostatic veins by the cautery. Prostatic patients with pyelitis often are in a state of chronic sepsis (I am sure my patient was in that condition)—that is to say, streptococci circulate within their blood, but are not virulent enough to produce acute general infection: but as soon as traumatism takes place the locus minoris resistentiæ is established. In the coagulated blood, their best culture medium, the streptococci or the bacterium coli commune rapidly multiply and become more virulent. The proximal pole of the thrombus is the place whence absorption takes place and fatal systemic infection sets in.

Nevertheless I believe that in a case of death from sepsis as a result of Bottini's operation the infection will oftener make its way through the kidney or kidneys than through the wounds of the prostate gland. In the case of an old prostatic with secondary dilatation of the ureters and renal pelves from back pressure, the bladder and ureters and the renal pelvis or pelves are, in a physical sense, but one cavity: infected urine, if retained, easily reaches the kidneys. And even if ureters and renal pelves have not become chronically distended by the prostatic obstruction, the infection of these patients by way of the kidney is possible. The interesting experiments of Lewin and Goldschmidt[1] have demonstrated beyond a doubt that direct, we might say physical communication exists between bladder and heart in an opposite direction to that of the current of the blood. According to these experiments, soluble material (colored fluid, ultramarine) and insoluble material (air) can reach the right ventricle by way of the renal vein and inferior vena cava. Under certain conditions the ureteral mouth of even a normal vesical viscus can suddenly gape, its normal closure toward the kidney can become insufficient. By means of the difference in pressure between the bladder and renal pelvis, also of the antiperistaltic contraction of the ureter, the soluble as well as insoluble matter can now ascend from the bladder to the pelvis of the kidney, whence it enters the lymphatics, the veins, and the uriniferous tubules, and is conveyed to the right ventricle. Then the current of

[1] L. Lewin and H. Goldschmidt: "Kurze Mitteilung einer Beobachtung aus dem Gebiete der Nieren-Pathologie," Deutsche medicinische Wochenschrift, 1897, No. 38, p. 601. L. Lewin: "Der Uebertritt von festen Körpern und Luft aus der Blase in die Nieren und in entferntere Körper-Organe," Deutsche medicinische Wochenschrift, 1897, No. 52, p. 825.

blood transports the foreign substance into the other organs, principally lungs and liver.

By these experiments a path has been shown by which foreign substances, and much more readily, of course, infectious micro-organisms, may enter the general circulation. The experiments also tend to explain "the sudden appearance of a general systemic infection" after intravesical interference, the cause of the occurrence of which, in a pathologic sense, has hitherto been rather obscure. That such a retrograde wave within the uropoietic system is all the more apt to set in, if the cavities and canals of the latter are in a state of pathologic distention, is obvious.

I therefore am of the opinion that, if my patient did die of sepsis, the infection took place in the manner of Lewin's experiments. This taken for granted, one question yet has to be answered: Why did this septic infection set in after Bottini's operation? Why not sooner—for instance, after ordinary catheterization or after cystoscopy? I shall not venture to try and explain this, as it could be done only on basis of further hypotheses. But we shall perhaps be better able to understand it by assuming that in dividing the prostate down to the floor of the bladder and near to the membranous portion of the urethra, the galvanocautery struck a small inflamed focus within the prostatic tissue, which contained especially virulent micro-organisms; and that these, added to the other inhabitants of the bladder and renal pelves, sufficed to produce the explosion.

Further, after all other instrumental manipulations within the bladder—such as, for instance, cystoscopy, litholapaxy, etc.—we make it a rule, so as to have done our share to avoid infection, to irrigate the urethra and bladder after the interference, and let the patient, if possible, spontaneously void the injected fluid; while in Bottini's operation, having finished the work, we extract the incisor and stop right there. Now I believe that the early withdrawal of 200 or 300 c.c. of urine (which certainly is not sterile) from the bladder, and aseptic irrigation of this viscus a few hours after the operation, might possibly avert to a great extent the danger imminent from this source.

I have tried to explain the occurrence of the septic infection in my patient somewhat exhaustively, for the sake of avoiding as much as possible similar experiences in the future. That I thought of it a great deal can be imagined. In order to be just, however, the fact must be emphasized that Bottini has not lost a single case from sepsis, nor has Freudenberg, Czerny, or Kümmel; and their practical experience combined embraces over one hundred patients. My case evidently is an exceptional one; but it shows that Bottini's operation also has its deaths, and that it shares the risks involved in all the other operative methods so far proposed for the radical treatment of this grave trouble.

What I am anxiously waiting for now is a patient with complete retention, one who has been entirely or almost entirely a catheter slave for a long period. In perusing the literature of the subject, we find that it is this class of cases which has derived the greatest benefit from Bottini's operation. By means of the frequent slight reinfection, which almost always occurs when patients catheterize themselves, no matter how careful they may be, their system seems to have acquired a kind of immunity against an acute septic infection of the streptococci and other pathogenic micro-organisms which inhabit the bladder. Even with a pyelitis these patients will probably much better stand direct interference than those who have been only occasionally subjected to local treatment by their physicians.

I am sure we shall learn to select prostatic cases which are especially adapted for Bottini's operation; I also believe that we shall learn in course of time to pick out such cases as should be primarily subjected to operations on the spermatic cords or to castration, eventually also to prostatectomy. Much will have to be learned yet in that respect.

But certainly we can to-day say of Bottini's operation that it leaves the important anatomical parts absolutely intact, without destroying tissues which for certain periods of the life of the male subject are of great importance (vasa deferentia, testicles), and without sharing, to a great extent at least, the dangers of other radical operations (ligation of internal iliacs, total extirpation). It furthermore certainly appeals to our common sense that, if the mechanical division of a mechanical obstruction can be rendered a permanent one in a comparatively safe manner with the help of absolutely reliable instruments, the method must be a good one.

It therefore seems to me that Bottini's operation decidedly deserves to be given a careful and unbiassed test. Should it really prove to be of such great value in the greater number of cases of this dreadful, so frequently in its remote consequences fatal disease, it will become our duty to give this operation not only a firm place, but one of the first places on the stepladder of the multitude of operations so far devised for the radical cure of hypertrophy of the prostate gland.

A CASE OF ACUTE LEUKÆMIA.

By W. H. THOMSON, M.D., LL.D.,
PHYSICIAN TO ROOSEVELT HOSPITAL,
AND
JAMES EWING, M.D.,
ASSISTANT PATHOLOGIST, ROOSEVELT HOSPITAL.

Lena F——, aged twenty-one, married, American parentage; admitted to the Roosevelt Hospital, June 8, 1897. Family history good. Patient gave no history of previous illness: denied syphilis, and never had rheumatism. She says that she gave birth to a child seven months ago, and that she had not felt strong since. But she complained of nothing during her pregnancy, and was not anæmic before or just after labor, and had nursed her child.

The most striking symptom which she presented on admission was her extreme anæmia, as if she was in the last stage of pernicious anæmia—the mucous membranes being very pale; skin yellowish; tongue moist, pale, and tremulous; gums not swollen or bleeding. She had a high temperature, 105.6° F. on admission; pulse, 148, very small; respiration, 40. She was also quite emaciated. The urine was acid; specific gravity, 1.014; it contained no blood or albumin or sugar, but full deposits of calcium oxalates.

Her history was that she had suffered from frontal headaches for six months, but otherwise she was fairly well and able to be about until six weeks ago, when she was first taken with a sore throat which lasted for two weeks. Then the entire right arm became swollen, painful, and red. This state of the arm lasted for three weeks, and it gradually got well. Then pains came on in the back and legs. Three days ago, on rising in the morning, she fainted and fell, when she struck her left side, which accident was followed by severe pain in the abdomen, extending to both sides, but especially the left. On palpation there was tenderness, but it was diffused and not localized. The pain remained constant, and was aggravated by deep inspiration. There was pain also on pressure at the eleventh and twelfth dorsal vertebræ. She had no vomiting and no cough, no dyspnœa, palpitations, or œdema; appetite fair, bowels costive, rather increased frequency of urination. On the night of her admission, however, she experienced a sense of choking and became short breathed. On examination her lungs were

found normal, there was a loud systolic hæmic murmur in the pulmonary area, the spleen could scarcely be felt, and there were no enlarged lymphatic glands palpable, nor were there any cutaneous ecchymoses visible.

As she appeared very much like one who had suffered from great loss of blood, a possible internal hemorrhage from rupture of the spleen after her fall was suspected. But, aside from the general abdominal tenderness being more marked on the left side, nothing could be made out, while continued internal bleeding appeared negatived by her pronounced pyrexia.

The first blood count, made the morning after admission, was 1,400,000 red cells per cubic millimetre; hæmoglobin, 27 per cent. The next day, the 9th, her temperature fell to 102.4° F. in the morning, and rose to 105° F. at 3 P.M. On the following morning it fell to normal; then rose to 102° F. at 3 P.M., and repeated these figures on the 11th, 12th, and 13th. On the 14th and 15th it gradually rose till it reached 104° F. on the 16th. It then fell gradually to 98° F. on June 19th, when she died.

Meantime her stomach became irritable, with continued nausea and repeated attacks of vomiting, from the 11th to the end of her illness. On the 15th she complained of much pain in her left arm, with local heat and tenderness, but no redness. She became unconscious twenty-four hours before death, and during the previous night a considerable patch of ecchymosis appeared upon the nose.

The following is the record by Dr. Ewing of the examinations made of her blood, of the autopsy, and of the microscopical appearances of the various tissues:

Acute leukæmia.—Date of receipt, June 19, 1897. Name of patient, Finnegan. Source, Roosevelt Hospital. Clinical diagnosis, acute leukæmia (?). Date of death, June 19th. Date of autopsy, June 19th. Autopsy by J. Ewing. Anatomical diagnosis: Leukæmic infiltration of marrow, spleen, liver, abdominal lymph nodes; anæmia. Material, all viscera. Preservation, formalin (Müller).

Examination of blood, June 10th: Red cells, 1,290,000; hæmoglobin, 20 per cent. There are but slight differences in the size and form of the red cells. There is a very marked leucocytosis. Of the leucocytes, 5 per cent. are myelocytes of medium size, containing rather scanty neutrophile granules. No nucleated red cells are seen. In the absence of a count of the leucocytes it may be said that they were not more numerous than is ordinarily seen in infectious diseases and probably numbered less than 50,000 per cubic millimetre.

June 15th, the red cells are as before, June 10th, but normoblasts are now abundant. The leucocytosis has increased and is now extreme, although the numbers probably do not exceed 100,000. Of these the proportions are: mononuclear leucocytes (lymphocytes), 33 per cent.; myelocytes, 12 per cent.; polynuclears, 55 per cent. An occasional eosinophile cell is seen.

June 19th, immediately after death. Normoblasts are very abundant. A good many megaloblasts are present, with single spherical nuclei. The leucocytes are very abundant, more so than on June 15th, but yet not nearly so numerous as in the average case of leukæmia. Mononuclears, 17 per cent.; myelocytes, 32 per cent.; polynuclears, 48 per cent.; eosinophile cells, 3 per cent. The granules and nuclei of the myelocytes are indistinct, and the polynuclear cells are very deficient in neutrophile granules and often in chromatin. It is possible that some hyaline leucocytes were enumerated as myelocytes in this estimate. No eosinophile myelocytes were seen. No distinct mast cells could be found.

Autopsy, June 19, 1897, one hour after death. Body emaciated, very anæmic. No rigor or œdema.

Heart: Size, valves, chambers, normal. Muscle very fatty. No signs of leukæmic infiltration.

Lungs: Very anæmic, otherwise normal.

Spleen: Moderately enlarged, very firm, elastic. Section very deep red. Malpighian bodies dark, shiny, indistinctly limited.

Liver: Consistence very much reduced. Slightly enlarged. Centres of lobules, homogeneous, pale; peripheries, deep red. There are very numerous, minute, pale or faintly gray foci, resembling the focal necroses of infectious diseases.

Kidneys: Size normal; surface smooth, very pale, fatty. Markings very irregular. Capsule not adherent.

Pancreas and adrenals normal.

Stomach: Mucosa shows a few ecchymoses. Gastro-intestinal tract otherwise normal. Neither Peyer's patches nor solitary follicles are enlarged.

Uterus rather small. Mucous membrane normal.

Ovaries normal.

Blood: No clots in vessels. Shed blood clots fairly well. Anæmia very pronounced. Abdominal lymph nodes—mesenteric, intraperitoneal, periportal—are slightly enlarged and hyperæmic. The superficial chains are nowhere enlarged.

The liver shows an enormous number of collections of large mononuclear cells, which usually appear to be in connection with the central veins. They show all stages of a peculiar necrosis characterized by extreme karyorhexis, without actual loss of chromatin and without a trace of inflammatory reaction in the neighboring cords of liver cells. The liver cells are otherwise markedly fatty. There is no infiltration in the portal canals. The necrotic process in the leukæmic foci strongly resembles the focal necroses seen in rabbits after the injection of large amounts of bacterial toxins, but the destruction of the cells is much less complete than in these experimental lesions.

In the kidneys, in the region of the arched vessels, are some foci of large round cells. The tubule cells show acute degeneration very marked in places.

The gastro-intestinal tract presents no lesions in any part of the wall. The lymph nodules throughout present normal appearances, although the sinuses appear rather cellular, and the blood-vessels here as elsewhere contain an increased number of leucocytes.

Marrow: The shaft of the femur contains almost diffluent, light-colored, bloodless marrow, which is with difficulty distinguished from pus on the one hand and fat on the other. Its physical properties are those of ordinary caseous material.

In the ribs, sternum, ilia, vertebræ, clavicle, hyoid, and humerus, the marrow is light colored and anæmic.

The nervous system appears normal.

Anatomical diagnosis: Leukæmic deposits in spleen, liver, abdominal lymph nodes, and marrow. Acute degeneration of liver. Fatty degeneration of kidneys, heart muscle. Anæmia.

Microscopical examination. Lymph nodes: Lymph sinuses and nodules partly or entirely obliterated by infiltration with large mononuclear cells. These grow diffusely through the node, often giving the appearance of sarcoma. The capsules of the nodes are intact. The vessels are usually gorged with blood. No bacteria are seen.

Sections of the marrow of the femur, at its middle point, show entire absence of fat cells and diffuse growth of large neutrophile myelocytes. There are very few giant cells, eosinophile cells, or lymphocytes. The sections of marrow from other localities are similar in appearance.

In the spleen the Malpighian bodies are largely replaced by collections of large mononuclear cells, which substitute the small lymphocytes normally found in these bodies. The splenic sinuses are moderately in-

filtrated with large mononuclear cells, and the splenic cords contain a considerably increased number of these cells. To these two latter changes the enlargement of this organ is due. The vessels and sinuses are moderately filled with red cells. Pigment deposit is moderate.

The pancreas appears normal.

The adrenals are normal.

The heart muscle is very fatty, but there are no distinct foci of round cells.

In the spinal cord there were no leukæmic deposits found.

It will be seen that the clinical features of this case rendered a definite diagnosis at first somewhat difficult. The signs during life, including the recent development of urgent symptoms, the extreme anæmia accompanied by such a high degree of pyrexia, the absence of any notable enlargement of the spleen, or of the liver, or of the lymphatic glands, conjoined with absence of signs of local inflammation in any important viscus, were also matched by the uncertain import of the macroscopical findings at the autopsy, from which the first report received was that the anatomical diagnosis was acute yellow atrophy of the liver, with fatty kidneys and heart, and a condition of the blood like pernicious anæmia. The first examination of the blood during life was also negative, for though there was increase of the white cells, yet the degree was not more than in the common leucocytosis in many febrile diseases. Therefore, without a subsequent microscopical examination of the blood and of the tissues, the essentially leukæmic nature of the affection could not have been recognized. On the first examination of the blood the appearance of myelocytes was doubtful, and there were no nucleated red blood cells seen. On the second examination, five days afterward, there was increased leucocytosis, red nucleated cells were abundant, and true myelocytes were demonstrable. On the blood examination after death the leucocytosis was still not nearly so pronounced as in ordinary cases of leukæmia, but the characters of the cells were unmistakable, including nucleated red cells, myelocytes, megalocytes, and large eosinophiles.

A great increase in the white corpuscles is, therefore, not necessarily characteristic of this specific disease, leukæmia, the diagnosis being dependent rather upon the presence of such special forms of cells as the myelocytes. In this case also it was the tissue infiltrations which were the most distinctive and pathologically the most significant. Besides the changes in the bone marrow, it is interesting to note that in the liver were numerous deposits similar to the necrotic changes in this organ caused by the toxins of diphtheria. It is in cases of acute rather than in chronic leukæmia that we find so much which is suggestive of a primary infective etiology. The unique case reported by Obrastow, of a ward tender who had charge of a patient suffering from acute leukæmia, and who, forty days later, was attacked by the disease, both patients then running a similar course to death, may have been only a coincidence, but it must be admitted that many histories of the acute form of this infection correspond more with infective processes than with any known form of systemic diseases. The specific agent, however, and its mode of entrance are entirely conjectural, though the occurrence of leukæmia in the lower animals, irrespective of the nature of their food, whether they were herbivora or carnivora, rather negatives the supposition of the alimentary canal being the channel of the infection, unless by means of drinking-water. The initial sore throat, however, in this patient, for some two weeks before any other symptom, and then the involvement of the arm, with subsequent subsidence before other developments elsewhere, offer some analogies to the infection of diphtheria.

INFANT FEEDING AND FOODS.[1]

By J. FRANK KAHLER, M.D.,

QUAKER CITY, OHIO.

My excuses for this oft-repeated subject are its importance at this season of the year and the hope that I may drop at least one thought of service. There is no cause for infant mortality so great as improper foods and feeding, and when we consider that about one-sixth of the human race die within the first year of life—or the period which I shall consider infancy in this thesis—we may appreciate the importance of infant feeding, as at least one-third of the above mortality is due to lack of care of the infant. A few mothers give birth to children who cannot nurse them, while many there are who will not nurse them, perhaps because of imaginary social duties or because they think the task of artificial feeding easier than natural feeding. To impress mothers with the importance of nursing properly their infants, the writer considers it a duty to tell them, when making his last visit after accouchement, these facts: "Long life of your child will depend very largely on the manner of feeding during this first year. Indeed, I am convinced that with the proper care during this period you will add at least five years to its existence, and not only this, but it will be much more likely to enjoy good health during middle life." Let us first try to impress upon mothers the truth that they will be saved many hours of wakefulness, anxiety, and perhaps agony, by regular habits in feeding infants, and supply, if possible, nature's food for at least the first six months of their existence. Nothing else except this and water.

Infants should, generally speaking, depending some on weight and vitality, be fed every two hours from 5 A.M. to 10 P.M., until they are three months old; every three hours until six months old; and every four hours until weaned at eleven months.

In order that we may do the most good for a given case afflicted with some form of bowel trouble, it is essential that we determine: 1st. The kind and manner of food given. 2d. Condition of discharges and frequency. 3d. Constitutional symptoms, if present.

The kind of diet prescribed will depend wholly on the condition of the discharges and the constitutional symptoms.

Vomiting frequently, with rather a cachectic expression, would indicate gastric trouble; while a fretful, anxious look, accompanied by tenderness in the umbilical region and thin but not frequent stools, would indicate enteritis. Colitis is accompanied by frequent muco-sanguineous discharges and tenesmus, with small actions and often a peculiar musty odor. If the inflammation involves nearly all of the alimentary tract, we have the above symptoms present in an aggravated form. Of paramount importance it is to know:

1st. The chemical reaction of the alvine discharges, *i.e.*, whether acid or alkaline, and for this purpose I always carry litmus paper with me. If the reaction is excessively acid, we may know this is due to the carbohydrates; consequently the cessation of this class of foods would be indicated; if very alkaline we may infer at least that this is due to the ingestion of the albuminous foods, and these should be forbidden.

2d. The color. If this be green, we may infer that the infant has eaten too much of the albuminous foods or has taken its milk too fast; consequently the casein has not been digested, and is an excellent culture medium for the germs which produce the green color.

3d. Odor. If this is scarcely perceptible, or slightly sour, the cause is certainly the starchy foods, while if very offensive it must be due to the proteid foods.

4th. Consistence. If the discharge is very thin,

[1] Read before the Guernsey County Medical Society.

with little mucus and no blood and not very frequent action, this would indicate that the seat of the trouble is in the small gut; while if the consistence is somewhat heavier and the discharge contains mucus with perhaps some blood, accompanied by tormina and temesmus, the lesion is in the colon. If in the colon, intestinal lavage is indicated with an astringent solution, such as chloride of zinc or a decinormal sterile salt solution. If in the small gut, astringents should be given by the mouth, such as arsenite of copper or bismuth.

5th. Digestion. If solid particles are seen we may at once determine what food to withhold, or at least modify the manner of feeding it.

6th. Constitutional symptoms. If there is a high temperature, it is certainly due to the albuminous foods, for the carbohydrates do not produce marked constitutional symptoms. Therefore the indices to the kind of food required are the location of the trouble, the chemical reaction, and the odor.

Foods are divided into four great classes, two of which only we need consider here, viz., proteid or albuminous and carbohydrate or starchy foods.

In the infant under three months the salivary secretion is very limited, and it is not at all abundant until in the seventh month; and, since this secretion does not act on raw starch at all, we may draw our own conclusions. Pancreatic secretion acts on raw starch; but this is not formed in the infant under four months. Therefore if an infant is disturbed with gastritis accompanied by diarrhœa, the actions being acid and not offensive, we may be positive that the carbohydrate foods are producing the disturbance.

In all cases of bowel trouble the writer believes it best to begin anew, *i.e.*, thoroughly to clean out the alimentary tract with one-fourth of a grain of calomel every hour until the desired effect is obtained, when the actions are offensive; or with oil when they are not offensive. Then give the kind of food indicated, with medication if this be needed.

We may have green discharges after feeding the starchy or proteid foods, because this color, as stated before, is very often due to germ action, and an excellent way to neutralize this condition is by the dilution of food with lime water. I trust I have now made clear the guides by which we may determine the kind of food indicated. I shall therefore first take up the carbohydrates and the manner of preparing them.

Flour ball: Put one pint of flour in a linen sack, add enough salt to season, and boil for twelve hours, after which remove the pasty part around the ball and grate the central part, to which add enough boiled water to make it of the consistence of cream, and feed.

Oatmeal or barley water is made by taking one tablespoonful of either, crushed, to which add one pint of hot water and allow to simmer for thirty minutes; strain and use. The former has slightly laxative properties, while the latter is slightly astringent and will aid in more lightly coagulating milk albumin or casein. I think the best proportion in which to use either of the above waters or plain water with milk is, for the first two months of an infant's existence, one part milk and two parts of water; third and fourth months, one of milk and one of water; fifth, sixth, and seventh months, two of milk and one of water. Great dilution not only aids the natural juices but also aids in the elimination of poisons.

Rice grains, one tablespoonful boiled in one quart of water for two hours; strain and add one-fourth this quantity of plain milk and one teaspoonful of cream.

Peptogenic preparations used in digesting milk have a similar effect on the actions, and are therefore contraindicated when the actions are excessively acid.

Milk whey is often assimilated when the discharges are alkaline and constitutional symptoms are present. The rennet necessary to separate the casein may be procured at any drug store.

Albuminous foods: Light beef, mutton or chicken broths, cream or whole milk (*i.e.*, with its casein) diluted.

Albumen water, prepared by adding the white of one egg to eight ounces of boiled water.

In the process of growth an infant requires a larger proportion of albumin to starch than does an adult.

I shall close, knowing that if we remember the following, as Rachford gives it, we shall be the more able to cope with infant bowel troubles: Poisonous ptomains are formed by fermentation of albuminous food and not in carbohydrates. Therefore we find constitutional symptoms in diarrhœa accompanied by fetid stools, but not constitutional symptoms in diarrhœa due to starch fermentation.

STREPTOCOCCUS ENTERITIS: A STUDY OF TWO CASES.

By E. LIBMAN, M.D.,

NEW YORK.

History.—Escherich, in 1886, in his celebrated researches on the bacteriology of the fæces of the healthy suckling child, found several varieties of streptococci. It is only of very late years, however, that attention has been paid to the rôle of the streptococcus in causing gastro-intestinal disease. Beck[1] described, in 1892, the case of an adult having cholera-like symptoms, in which case he found streptococci in the movements and in the blood. De Cerenville[2] reports three cases which looked like atypical typhoids; the stools contained numerous streptococci. Tavel and Eguet[3] observed a number of cases in which a streptococcus seemed to have been causal, and divided them into three sets: first, those that were typhoid-like; second, those that were choleraic; and third, those that presented the picture of a septico-pyæmia. Either set could be acute or chronic. All the above-mentioned cases occurred in adults.

Booker[5] was the first to draw attention to the same class of cases in children. In his exhaustive treatise he divides summer diarrhœas into three classes: first, dyspeptic diarrhœas, in which the bacilli coli communes and bacilli lactis aerogenes predominate; second, bacillary gastro-enteritis, in which a variety of other bacilli is found; third, streptococcus gastro-enteritis, which is characterized by symptoms of a general infection. The first work on the differentiation of the streptococci in such cases was done by Hirsch,[4] of Baltimore, working in the clinic of Escherich, in Graz. In the case he described he found a streptococcus hitherto unknown. Through the kindness and under the direction of Professor Escherich, whom I sincerely thank, I was enabled to study two cases of diarrhœal disturbance in which the streptococci isolated by Hirsch were present.

Case I.—Clinical history: The first child, two and one-half years old, was suddenly taken sick, with a temperature of 106° F., vomiting, and diarrhœa. The vomiting ceased after a few hours. During the first three days of the illness the number of the movements, composed mainly of greenish mucus, pus, and blood, averaged twenty daily. More minutely described, the movements consisted of three parts. The first was leek-green mucus (this part contained most of the streptococci). The second was made up of white streaks of pus, dotted with blood. The third was gray mucus, also dotted with blood. The child was apathetic and somnolent. On the evening of the first day it had two convulsions. The abdomen was always soft and contracted.

After the first day the temperature remained at about 100° F., except for a rise to 103.5° F. on the third day after this; the number of stools gradually diminished, and they became more and more feculent. Thenceforward the convalescence was uninterrupted. At the onset the urine contained a trace of albumin. There was also present in the blood a moderate polynuclear leucocytosis. The therapy consisted in regulation of the diet, tannalbin, and high enemata of liquor Burowi.

Bacteriology: In the early stools there were, microscopically, swollen and fatty epithelial cells, fat crystals, red blood corpuscles, mucus, and pus cells. Stained according to Weigert (Escherich's modification), there were seen numerous streptococci, later to be minutely described, and bacilli. The later stools contained streptococci almost exclusively, the same being confined mainly to the mucous portions of the stools. After the third day, coincident with the improvement of the child, the streptococci in the stools diminished, and a day later were absent. Cultures from the blood and urine remained sterile. A mouse subcutaneously inoculated with a small amount (a few cubic millimetres of the fæces) died after sixty hours, and in its blood, microscopically as well as by culture, the streptococci were found.

Case II.—Clinical history: The second child, eight months old, on admission to the clinic had an attack of vomiting followed by a severe diarrhœa. For several days previously it had had frequent mucous movements. After admission it had seven to ten stools daily, of the same character as those in the last case. The temperature at the onset was 101.5° F., later it rose to 102° F., after which it was subnormal. The urine was markedly albuminous and scanty. The abdomen was soft and retracted. The head was retracted, the neck stiff. After three days the child succumbed, having been stuporous almost constantly.

Post-mortem examination: At the section, made four hours after death, there was found a fatty degeneration of the heart, kidneys, and liver. The spleen was slightly enlarged. The gastro-intestinal tract as a whole looked pale. The stomach showed slight hemorrhagic erosions, and contained material like coffee grounds.

The mucous membrane of the small intestine was swollen, and presented pin-point hemorrhages. The Peyer's patches were swollen. The most marked changes were just above and just below the ileo-cæcal valve. The mucous membrane there was distinctly thickened, the follicles were swollen, and here and there were small defects.

The microscopical examination of the parts gave, in short, the following: In the stomach there were areas of small round-celled infiltration in the submucosa, above some of which the tubules were missing. There was also marked intraglandular inflammation. In the small intestine there were inflammatory changes in the intraglandular tissue. Here and deeper down, to the serosa, were streptococci in small numbers.

Just above and below the valve there was a marked cell infiltration between the glandular tubules. The follicles were markedly swollen, some being capped by small substance defects. On the surface of the latter and in the submucosa and muscularis were numerous streptococci.

In the lungs, in places there was a small-cell infiltration in the interstitial connective tissue, around the smaller vessels, and also some desquamation of the epithelium lining the alveoli near by. Cocci were present in the lumen of the vessels and in their surroundings. The heart, liver, kidneys, and spleen also contained streptococci.

Bacteriology: An examination of the early stools in this case revealed a colossal number of streptococci, and this find remained constant. Two hours ante mortem cultures were made from the blood and urine. In the former streptococci alone were found, and in the latter streptococci and coli bacilli. From the fæces an agar plate was poured, and by inoculating from this into sugar bouillon a pure culture of the streptococci was obtained. A mouse inoculated subcutaneously with one cubic centimetre of this culture succumbed in forty-three hours, the blood showing numerous streptococci. Before death the movements were soft and numerous, and contained the cocci. In the case first detailed, pure cultures were obtained by the method just mentioned. These resembled closely those present in the second case.

General Remarks.—The streptococcus found in these two cases corresponds to that described by Hirsch. In the fæces it appears as a flattened coccus, in short straight chains or angular chains, the diplococcus arrangement being frequent. In sugar bouillon, after twenty-four hours there is a uniform cloudiness; after five or six days the upper part of the fluid clears. The growth is less active in ordinary bouillon. In bouillon the coccus appears frequently in groups of two or three. In longer chains, one of the chains is apt to be larger. The average size of the cocci, stained in fuchsin, is 0.75 μ by 0.9 μ. The coccus stains with Gram.

On gelatin only the cocci from the second case grew, probably due to their greater vitality. On the surface of the gelatin there is a slight, faint, translucent white growth. In stick cultures there result discrete transparent points along the line of inoculation; occasionally there is a little continuous growth. On plates after forty-eight hours there are small, translucent white points, just visible to the naked eye. Under the microscope these appear as fine, light yellow points and discs of irregular form, with dark granular centres. The colonies reach a size of about 0.1 mm. in diameter, and spread no farther. In most cultures on gelatin there was a slight liquefaction.

On agar plates the colonies, microscopically viewed, are irregularly oval, coarsely granular, with a finely dentated edge; the centre is darker and yellowish. After twenty-four hours there is no further growth.

Milk is acidified after one day, and solidly coagulated after five or six. On potatoes there is a moderate growth, with active cultures, which appear in the form of isolated white colonies, which may later run together.

On agar, covered with a coagulated layer of human blood serum, there is a very abundant growth. In such cultures the cocci are apt to be arranged in larger groups, rather than in chains. The cultures thus obtained are very vigorous, giving, on agar and potatoes, thick, creamy growths. With them milk is coagulated after one day, instead of after five or six days, as before.

Mice were fed with such cultures in bouillon, on bread or mixed with milk. All had very frequent movements, consisting mainly of mucus, with a little pus, and in one there were some blood points. These mice died in varying lengths of time, from thirty-three to one hundred and three hours, depending on the number of generations from the cultures on serum the bouillon cultures were removed. The intestines, post mortem, always showed more or less marked inflammatory changes, and the cocci were found in the blood in small numbers.

Subcutaneously inoculated, one cubic centimetre of such cultures caused the death of mice in from forty-eight hours to eight days. Those that lived over two or three days had diarrhœal movements. Post mortem, the cocci were found in the blood and in some of the movements.

Experiments to show any existing antitoxic or bac-

tericidal action of the blood serum of the child that recovered gave no decided results.

A REPORT ON FIFTY-ONE INTRAPERITONEAL OPERATIONS, SUPRAPUBIC AND VAGINAL, WITH TECHNIQUE.

By P. F. CHAMBERS, M.D.,

NEW YORK.

While fully recognizing the many reasons for unreliability of medical statistics, we must still accept them as the only possible guide we can have. We know the ease with which they can be warped to suit the condition and the prejudiced opinions of the operator. We know, too, that even when correctly and conscientiously submitted, there is always likelihood—owing to a run of very favorable cases—of doing more than justice to an operator. On the other hand, there is likelihood of injustice through a number of unfavorable cases.

Notwithstanding this, I unhesitatingly submit a report on the last fifty-one cases of intraperitoneal operations which I have consecutively performed at the Woman's Hospital, in my private practice, trusting thereby to emphasize a few points of technique which I have found to be of value.

A glance at this series of cases will show a good variety of operations which properly fall to the domain of gynæcology. They were in no way selected; simply taken as they came, none being rejected on account of malignancy, nor for any other reason that might affect the record.

Of the fifty-one operations, twelve were for removal of ovaries and tubes, fifteen for vaginal, and fifteen for suprapubic hysterectomy. The remainder were for ventral suspension and removal of one ovary and tube, abdominal shortening of the round ligaments, appendicitis, and vaginal oöphorectomy. The last operation (and the only fatal one) was for the removal of a fistulous tract, which I supposed led down to a ligature left at a previous operation performed by another surgeon two years before, but which proved to be a small, deep-seated septic abscess. Septic peritonitis quickly followed the operation, and the patient died in twenty-four hours.

The operation for the removal of ovarian cysts was a frequent one ten or more years ago, and was then so thoroughly performed that there have been very few changes in the technique, and in my judgment the changes have not been for the better.

But in the method of removing pus tubes, and especially in hysterectomy—both vaginal and suprapubic—I think the improvement has been very great. In suprapubic hysterectomy the clamps and the extraperitoneal treatment of the stump were first discarded, and the disuse of the metallic and non-absorbable ligature soon followed. The next advance has been made in discarding as much tissue from the ligature as possible; in other words, in trying to catch the arteries only in the ligatures, instead of a mass of tissue containing ligaments, nerves, and occasionally uterus. By this method there is as little as possible left to slough.

In the vaginal operation the last-mentioned improvement is much more difficult than the old method, but by the exercise of a little additional patience and some care in applying the clamps or ligatures even in this operation very little tissue needs to be involved. By enucleating or dissecting off the uterine artery, a clamp or ligature can be easily applied to the ovarian artery, and usually that is all that will be found necessary.

In suprapubic hysterectomy I have found the following method the most rapid and satisfactory in every way:

The abdomen being opened by a free median incision, and the patient placed in Trendelenburg's position, the uterus is drawn up as far as possible out of the pelvis. Two clamps are then applied upon the broad ligaments of one side, one near the uterus, the other to the parietal side of the ovary, the point of the latter touching the uterus. An incision is then made between the clamps, down to the point of the outer clamp, without loss of blood. After the same procedure is repeated upon the other side, an incision can be made across the anterior surface of the uterus from clamp to clamp, freeing the peritoneum and posterior bladder wall, which then can be easily peeled off down to the vaginal junction with the operator's finger nail or the handle of the scalpel. The uterus is then cut across and removed.

In the great majority of cases the two clamps left, one upon each broad ligament, will be found to have controlled all hemorrhage; and protruding from between the jaws of the clamps will be seen the open mouths of the blood-vessels. These can be easily picked up by artery forceps, and after the clamps are removed ligated with small chromicized catgut. By the use of the Paquelin cautery the cervical canal is enlarged, and with a small piece of iodoform gauze drainage is established through into the vagina. The peritoneal layers are then brought together by running catgut suture antero-posteriorly, so that the stump is covered and all raw surfaces are inclosed. The abdominal incision is closed with one line of silkworm-gut suture.

The operation is easily performed; it leaves a good floor to the pelvis, and there is no sloughing from the ligatures. Patients can usually sit up within ten days.

I have not used a silk ligature for more than a year; and while I do not consider the catgut an ideal one, it is still the best we have.

The suprapubic operation for the removal of pus tubes is performed after practically the same method. The tubes being held up by the fingers of the operator or by forceps, clamps are applied just below, and the tubes and ovaries are cut away. The arteries are picked up and ligated in the same manner as in the operation for hysterectomy, and the raw surfaces covered by bringing the peritoneum over with the running catgut.

The clamps in vaginal hysterectomy are for many reasons very objectionable. They cause considerable slough and are very uncomfortable, but in several of my cases they were indispensable; and in all they very materially shortened the operation, which in itself is a great consideration. I have never had any sepsis following their use, and have considered the drainage better than it would have been with gauze alone.

Vaginal oöphorectomy.	Pyosalpinx	1	2 cured.
	Ovarian cyst	1	
Suprapubic oöphorectomy.	Chronic salpingitis and ovaritis.	4	12 cured.
	Ovarian cyst	2	
	Pyosalpinx	6	
Vaginal hysterectomy.	Carcinoma uteri	4	15 cured.
	Ectopic gestation	1	
	Salpingitis and ovaritis (septic).	5	
	Pyosalpinx (with adhesions)	2	
	Fibroma uteri	3	

Suprapubic hysterectomy.	Fibroma uteri	9	15 cured.
	Pyosalpinx	5	
	Ovarian cyst	1	
Vaginal cœliotomy for removal of appendix		1	—Cured.
Herniotomy—large hernia, result of a previous laparotomy		1	"
Hysterorrhaphy and removal of appendix		1	"
Hysterorrhaphy and removal of one ovary		1	"
Nephrectomy for pyonephrosis		1	"
Abdominal shortening of round ligament		1	"
Removal of fistulous tract and pelvic abscess		1	—Died.
Total		51

Progress of Medical Science.

Shock I admit is often very severe after operations upon the urinary organs and especially upon the kidneys. I have been told by Dr. Hewitt that he has several times known the pulse to fail at the moment that the ligature was tighened around the pedicle in performing nephrectomy.—Moullin.

Erythromelalgia a Symptom of Syringo-Myelia.—A recent observation, reported by Pospeloff, is interesting because of the association with syringo-myelia, since it is recalled that several previous observers have considered erythromelalgia not as a distinct morbid entity, but as a syndrome met with in the course of various affections of the cerebro-spinal system, due to a lesion of the posterior and lateral cords of the medulla. The patient was a woman, thirty-six years of age, who entered the hospital with characteristic symptoms of the affection, including anæsthetic panaris. There existed also in the palm of the right hand, at the elbow and shoulder, and upon the same side, intense pain of paroxysmal character. There was also cyanosis of the hand, especially of the index and middle fingers, with dense and glistening skin. The palmar surface of these fingers showed more marked perspiration than other regions of the body. The temperature was two degrees lower than on the opposite side. The left hand became glossy, œdematous, and extremely painful, and the back of the hand became violaceous. Subsequently the same condition was noted in the left foot. Gonorrhœal and acute rheumatism were excluded. The term acute, painful, circumscribed œdema is suggested to distinguish such instances from acute circumscribed œdema of Milton and Quincke. Subsequently gangrenous herpes in bands, such as is seen in syringo-myelia, developed. —*La Presse Méd.*, November 10, 1897.

An Acquired Syphilis of the Heart.—Grassmann declares (*Münch. med. Wochenschrift*, No. 18–19, 1897) that, contrary to generally accepted opinion, acquired syphilitic disease of the heart is not rare. The reason it is observed so rarely is that the pathological anatomist, in post-mortem examinations, pronounces only those cases "heart syphilis" in which gummata are found. *A priori*, the syphilitic infection finds its way to the heart through the circulation, though nothing certain is known of the course of the infection. The diagnosis of "heart syphilis" during life is very difficult and can seldom be made with certainty. The writer has made the following anatomical and pathological studies: Isolated specific pericarditis never occurs, the pericarditis being caused by direct extension from the underlying fibrous or specifically infiltrated gummatous heart muscle; in this way are both the visceral and parietal pericardial layers attacked. In similar manner specific endocarditis is in almost all cases due to an underlying gumma in the myocardium. The disease almost never manifests itself as an endocarditis valvularis. The most important changes occur in the myocardium. Histologically speaking, the gummata occurring in the heart muscle belong to the so-called granulation growths; they vary from a microscopically small growth to the size of a chestnut. The development of a gumma in this situation is very slow, generally requiring years from the time of infection. If in these tumors cellular proliferation predominates, the nodules become soft, cystic, or undergo cheesy metamorphosis; if increase in intracellular substance predominates, the nodules become more or less hard. If through some cause absorption of the gumma takes place, an aneurism of the heart may develop at the site of the thus impaired and thinned myocardium; from such an aneurism eventual thrombosis and embolism, or rupture (and consequent death), may occur. Gummata are generally found in the left ventricle. When, in the neighborhood of a gumma, inflammatory processes in the myocardium are found, these latter are also due to the syphilitic infection; yet such syphilitic processes may exist without gumma formation. Regarding the clinical symptoms of "heart syphilis" (when the post-mortem pathological diagnosis has been made), all observers are agreed that the disease does not occur till at least ten years after the infection. The symptoms are not pathognomonic; they are identical with those of cardiac insufficiency from other causes. Hence one observes the symptom complex of heart failure, in all its phases: œdema, effusions into the peritoneal and pleural cavities, palpitation, dyspnœa, etc. As another symptom of "heart syphilis," sudden death during the enjoyment of apparent health must be reckoned. Generally the diagnosis is made by exclusion, *e.g.*, exclusion of alcoholic myocarditis, of fatty degeneration of the heart, of arterio-sclerosis, of previous rheumatism, etc. In isolated cases the diagnosis may be made directly by the certainty of a previous syphilitic infection, or by the uselessness of the ordinary therapeutic remedies for cardiac insufficiency. The diagnosis is made certain by the favorable result of antisyphilitic treatment. The treatment of "heart syphilis" is the same as that of syphilis in general. The treatment, however, should be slow and careful; if it be too energetic, harm may occur through the too rapid absorption of gummatous deposits.

The Relationship of Psoriasis to Gout and Diabetes.—Medical literature cites a few cases in which a relationship existed between gout and psoriasis, as well as between psoriasis and diabetes. In corroboration of this, Carl Grube (Neuenahr) mentions nine cases of his own in which the existing psoriasis developed on a gouty basis. He also mentions seven cases in which diabetes was connected with a gouty diathesis.

Splenic Tumor in Rachitis.—Dr. Von Starck says, in the *Archiv fur klin. Med.*, 57, 3 and 4, that in one hundred cases of rachitis the diagnosis of splenic enlargement was made sixty-eight times. The situation of the tumor is the same as in the adult. There is no ground for the belief that the spleen is relatively larger during the first year of life than in the later years of childhood, yet during the first year the spleen shows an extraordinary tendency to enlarge under pathological conditions. The splenic enlargement, in the cases of rachitis examined, was generally medium. There is no constant relation between the severity of rachitic bone changes and the amount of enlargement of the spleen; the latter is more constantly governed by the severity of the accompanying anæmia. Autopsies on rachitic children (when other causes of splenic enlargement, *e.g.*, infectious diseases, could be excluded) showed a splenic tumor in over fifty per cent. of the cases. The tumor was more generally found in those presenting marked rachitic bone alterations; yet

even if the latter be very severe the enlargement may not exist. The splenic tumor, either macroscopically or microscopically, shows nothing characteristic. The writer concludes that tumefaction of the spleen can hardly be considered a symptom of rachitis in children, and that it is caused by the same unknown noxious product that produces the rachitis.

Traumatic Diabetes.—Lenné reports ten cases in which trauma could be regarded as the etiological factor in the production of diabetes.—*Deutsche med. Wochen.*, 1897.

The Rôle of the Blood-Vessels and of the Parenchyma in Inflammation.—R. Virchow (*Virchow's Archiv*, Band 149, Heft 3) claims that inflammation shows itself as an irritation, both of the blood-vessels and of the nerves; of the specific as well as of the non-specific parenchyma. He differentiates four kinds of inflammation: exudative, infiltrating, parenchymatous, and proliferating. The irritation is generally of a chemical, occasionally of a mechanical nature. Proliferation is only a peculiar form of cellular power; it always implies the formation of new material. The "new material" need not be taken directly from the vessels, since this form of inflammation (the proliferating) likewise occurs where there are no blood-vessels; in the latter case the cells take their material from their surroundings through their power of attraction. Nourishment consists in the assimilation of the taken-up material, the cells having the peculiar innate elective power of absorbing from the neighboring tissues what is best suited to them at that time. Heat and redness do not occur in inflammation of non-vascular parts. Inflammatory redness is due to irritation of the nerves. The result of parenchymatous inflammation is fatty metamorphosis. This inflammatory fatty metamorphosis is to be distinguished from the non-inflammatory: the latter is due simply to nutritive disturbance. The former always implies, as a condition preceding the fatty change, either cloudy swelling or cellular proliferation, both caused by the attractive power of the cells. In conclusion Virchow remarks that the fibrin in inflammation can very often be regarded as the product of parenchymatous metabolism.

Case of Dermatosis Linearis Neuropathica.—Leven (*Deutsche med. Wochenschrift*, 1897, No. 41) reports the case of a sixteen-months-old boy in whom since the sixth week of life there existed on the posterior surface of the left lower extremity a band-like, dark red, elevated stripe, three millimetres to one centimetre wide, which, beginning about two centimetres inward from the greater trochanter, ran obliquely downward and inward to the bend of the knee, then made a short turn outward, and finally took its course along the lower part of the thigh and centre of the leg, to the heel. The stripe was covered with small scales and crusts, but did not present a warty or papillomatous character. In the immediate vicinity could be seen here and there red-brown papules the size of a pin's head, and an intense itching was present. Leven is of the opinion that the affection is due to a disease of the cutaneous nerves.

Hemiplegia Cerebralis Following Diphtheria.—Levi describes a case of severe gangrenous diphtheria in which after three injections of Behring's solution No. 3 an improvement of the local condition was noticed. During the first week endocarditis and nephritis complicated the condition, and urticarial wheals sprang up over the entire body. During the second week there arose paralysis of the soft palate, which necessitated the use of the sound for the nourishment of the child. Then suddenly followed an apoplectic result with left-side facial paralysis and paralysis of the extremities of the same side, and soon after that a second attack, with paralysis of the muscles of the neck. These paralyses are very rare in diphtheria—only thirty-four cases having been reported—and are probably the result of thrombosis in the right Sylvian artery.—*Wiener klinische Rundschau*, January, 1898.

Thrombosis of the Femoral Vein following Pneumonia.—Dr. Kob (*Deutsche med. Wochenschrift*, No. 13, 1897) reports the above case. The patient died suddenly while sitting up in bed, death being probably due to a detachment of an embolus.

Tuberculous Myocarditis.—To the Société Anatomique de Paris, Péron demonstrated numerous hearts in which, in addition to the tuberculous inflammation of the pericardium, there existed tuberculous areas in the myocardium. In animals tuberculous myocarditis is seen after the injection of tuberculin.—*Berliner klinische Wochenschrift*, January, 1898.

Intermittent Hydronephrosis.—Richardson (*Boston Medical and Surgical Journal*, 1897) reports a case of the above which was caused by the fact that the insertion of the ureter to the pelvis of the kidney was such that each time the latter was filled compression of the former resulted.

Complications of the Menopause.—According to the observations of Le Gendre (Société médicale des Hôpitaux, December 10, 1897) the menopause may give rise to certain disturbances in the circulation of the kidney, which in turn may cause various disturbances in the organism. In such cases the urine is suddenly diminished; slight albuminuria and transient hæmaturia may also exist. The women complain of vertebral pain, nausea, vomiting, and severe headache. These symptoms probably depend upon a retention of toxic substances, that is, upon an auto-infection. Venesection and diuretics are indicated in such cases.—*Berliner klinische Wochenschrift*, January, 1898.

Fourteen Cases of Mal Perforant Treated by Nerve Elongation.—A. Chipault (*Gazette des Hôpitaux*, 1897, No. 127) recommends nerve stretching as a cure for perforating ulcer of the foot. In order to procure a good result, he states that the elongation must be carried out neither too near nor too far from the seat of the ulceration. His method is as follows: First the internal and external plantar nerves are stretched either singly or together, then the external saphenous nerve is stretched; at the same time the ulcer is kept scrupulously clean. Its edges are sewn together and covered with an antiseptic dressing. In twelve of the fourteen cases Chipault claims to have brought about a cure. This method is also recommended for the treatment and cure of similar disturbances in amputation stumps, and in long-standing trophic skin diseases, *e.g.*, herpes.

Indications and Contraindications in the Use of the Schleich Local Anæsthesia.—Krecke (Munich) and Reichold (Lauf), as a result of an extensive experience with the Schleich infiltration anæsthesia, make the following statements: In operating upon healthy tissue, as it were, such as injuries of the fingers, amputation of phalanges, cleansing of incised wounds, circumcision, and tracheotomy, it is a most excellent method. For the anæsthetizing of inflamed parts, however, such as felons, furuncles, and the like, it is of little worth, since the operation is practically as painful as without the anæsthesia. Again the after-pain is often so marked and lasting that this method in inflammatory processes is to be condemned.—*Wiener klinische Rundschau*, January, 1898.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 5, 1898.

CASTRATION AS PUNISHMENT FOR RAPE.

A BILL to amend the existing statutes of Ohio, relating to the punishment of the crime of rape, has been brought before the legislature of that State and may become law. The object of this proposed amendment is to render a man who is convicted of a criminal assault upon any female, and particularly upon any child under fourteen years of age, liable to castration. How effectually to protect women and children from becoming the victims of sensual libertines or criminal degenerates has long been the aim of social reformers. That extreme measures are called for and that a punishment sufficiently deterrent is needed are obvious, as unfortunately offences of this description show no signs of diminishing. It is claimed by many that nothing short of asexualization will bring about the desired result. Castration was practised largely in very early times, and was then resorted to in order to limit the production of the human race. In Eastern countries the custom has prevailed from times immemorial. Many, too, of the early Christians submitted themselves voluntarily to mutilation as a means of mortifying the flesh, although the church authorities generally were averse to the practice. The opportunities of estimating the effect of castration, physical, mental, and moral, on man, are necessarily very few in civilized countries, and in order to gather trustworthy data the opinions of those who have lived in the East and made a study of the question there must be relied on. The physical effects of castration are similar in men and animals; those operated upon when young grow taller and larger, as well as more fleshy. M. Loitet exhibited before the Société de Médecine of Lyons the skeleton of a eunuch of Cairo. In this specimen the thorax was short as compared with the exceptional length of the legs. This phenomenon is quite in accordance with what is met with in the lower animals under like circumstances. Thus, while the wings of a capon are no more highly developed than those of a cock, the long legs of the emasculated fowl give it a peculiar appearance. This same lengthening of the hind limbs in the ox corrects the sloping of the back which is so characteristic of the bull. Gall and later Haschke have shown that in animals deprived of their testes when young there was an arrest of the development of the cerebellum, of the medulla oblongata, and even of the cerebral hemispheres. As to the mental effects of asexualization of man, opinions widely diverge. Most modern authors contend that eunuchs are in all cases weak minded; however, this view was not held by the ancient writers, nor is it by many observers of the present day. Dr. Edmund Andrews, of Chicago, says: "Some writers assert that if castrated young the eunuchs remain perfectly indifferent to female attractions, and articles are often written in medical journals advocating the castration of sundry criminals in adult life, under the assumption that their sexual temptations will all be removed by the simple ablation of the testes. . . . The fact appears to be that men castrated in adult life often retain a troublesome amount of sexual desire, and that even if it is done in childhood there is by no means a total absence of it, though it is much lessened." Dr. Louis Tercheron, the eminent French authority on medical jurisprudence, states that there is a physiological possibility of fecund coition after a castration has been performed on an adult. The opinions held in regard to the moral qualities of eunuchs are very conflicting. The majority of writers believe that the moral nature of these men is wholly perverted. M. Temturilie, in his work on the Skoptzy, a religious sect in Russia, who practise emasculation as one of their religious rites, says that these people, although susceptible of a certain attachment, are egoists, deceitful, liars, cunning, and greedy, but adds it is difficult to say if this is the effect of castration. Temturilie noticed among the Skoptzy an attenuated sense of responsibility, and this has been observed of eunuchs by many writers. Dr. Andrews is of the opinion that eunuchs differ little in moral qualities from the ordinary run of mankind. It seems, however, only reasonable to suppose that castration has a pernicious effect on the moral nature as well as on the mental and physical vigor of a man, although probably exaggerated notions exist on this point. Even allowing that ablation of the testes will remove sexual temptation, as doubtless it will in most cases, there will still remain among civilized people a strong prejudice against so degrading a punishment. The time may come when this matter will be viewed from a different standpoint, and when, as some predict, the operation will be esteemed necessary to stamp out many of the evils of modern civilization. As yet these advanced opinions will not receive general indorsement, and the action of the Ohio reformers will not commend itself favorably to the sense of the country at large. The use of the cat-o'-nine-tails has been found in England to act as an effective deterrent in the case of hardened criminals, and, while it is an inhuman form of punishment, it is preferable on the whole to that of castration.

The Compositor's Greek.—"Acoustics (derived from the Greek verb ἀκοὴω, 'to hear')" is the way an interesting article begins in one of our esteemed contemporaries. The Greek font was probably missing and the compositor did the best he could.

EGYPT AS A WINTER RESORT.

Egypt has gained an enviable reputation as a winter home for those who suffer from diseases of the respiratory organs. Every year, as the cold weather approaches, large numbers flock to the regions bordering the Nile, some on pleasure bent, but the majority imbued with the hope of deriving benefit from the exceptional climate. The ancients were well aware of the health-giving, medicinal properties of the climate of Egypt, although it is only within recent times that this fact has been appreciated and understood at its full value. The Roman physicians were accustomed to advise their patients to go to Egypt—by Egypt meaning Alexandria, as in those days the interior of the country was almost a *terra ignota*, owing to the difficulties of travelling. Herodotus makes mention of the salubrity of the air, and as a testimony to this points to the healthiness of the Egyptians. Naturally nowadays most of the visitors to Egypt are English, although latterly many Americans follow their example; indeed, during what is known as the Egyptian season, there are to be found gathered there representatives of nearly all the civilized nations. In view of this, it is a matter of great importance that thoroughly reliable information should be obtainable with regard to the variations of climate in different parts of the country. Some years ago, before accurate records of the varying degrees of temperature had been taken and tabulated, it was thought to be immaterial whether the sufferer lived in the cultivated valley of the Nile or on its western side in the desert. So long as the destination was Egypt, the particular location was regarded as an unimportant detail. Within recent times, however, the knowledge of the climate of Eygpt has been greatly extended, and now a physician is able to advise his patients as to the district best adapted to the necessities of their individual cases. Dr. H. E. Leigh Canney has just published a paper based upon the original research on the winter climate of Egypt which has been carried on during the past three or four winters. It has been already pointed out by the author in a former paper, read before the International Medical Congress at Moscow, that there are great differences in the local conditions of the Egyptian climate, and that these local conditions are for the most part modifications of the Libyan desert climate, produced by varying amounts of cultivation and varying distances from the Mediterranean Sea. The effect of cultivation on the temperature as stated by Dr. Canney is to produce a rapid rise of the latter immediately before sunset, and for the following two or three hours to maintain a fall, and to attain a far lower minimum than that reached at stations only slightly influenced by cultivation, so that at 6 A.M. a difference of fifteen or twenty degrees may be found at stations a mile or two apart. On the other hand, the course of the temperature in the desert is uniform and much less subject to the more or less sudden variations which mark that of stations in or under the influence of cultivated land. Dr. Canney goes on to say: "The feature of the Egyptian climate which has always attracted the most attention is the dryness of the air, and this has been the more noticeable in Upper Egypt, where the rainfall is hardly measurable. If the relative humidity is considered, there is no known health resort which can even approach the climate of Upper Egypt in dryness: it is even considerably dryer than the high altitudes of Colorado." The cases deriving the greatest benefit from the climate of Egypt are, according to the conclusions arrived at by medical men who live in Egypt and have made a study of the subject, mostly diseases unknown or rare in that country, as phthisis, asthma, bronchitis, gout (and its attendant disease of the arterial, renal, and cardiac organs), Bright's disease, insomnia, rheumatoid arthritis, dyspepsia, and sciatica; while the list of unsuitable cases given are phthisis, with very acute symptoms or tendency to diarrhœa, or repeated pleurisy, or involved larynx, or active disease of both lungs, all heart affections, chronic diarrhœa, tuberculous kidney.

ARE WE TO HAVE OSTEOPATHY IN NEW YORK STATE?

Quacks have always existed, and the prediction may be safely made that they always will exist. People willing and eager to be deceived abound everywhere, and it is by playing upon this well-known human weakness that the end-of-the-century charlatan is able to demand and receive such preposterous prices for his worthless "nostrums," and at the same time to rob a too-confiding public and the unfortunate doctor. To this condition of things the medical profession as a rule submits as a matter of course and endures with stoical philosophy; but the enterprising Christian scientists, faith healers, professors of osteopathy, purveyors of ointments and pills, and the other members of the irregular fraternity are not content with the scope of their present field of action. It is too restricted for the exercise of their abilities, and now, forsooth, they have the audacity to demand protection by law!

With this object in view, a bill has been introduced into the legislature of New York State to regulate and legalize the practice of osteopathy. This bill has been drawn with much subtlety, and is well calculated to delude the unwary into the belief that osteopathy is a more or less legitimate branch of medical science. For instance, a portion of the bill reads as follows: "Any person having a diploma or certificate of qualification regularly issued by any incorporated and regularly conducted school of osteopathy, and who shall have been in personal attendance as a student in such school for at least four terms of not less than five months each before receiving such diploma or certificate, shall be authorized to treat diseases of the human body according to the osteopathic method." In fact, this is a bold attempt, on the part of persons who have received no regular training, to creep in by a back door, in order to share in the privileges now granted only to those who by a long course of study and by passing severe examinations have proved themselves capable of treating human diseases.

It will be remembered that last year the legislatures

of South Dakota, Colorado, and Illinois passed a similar bill, which the respective governors of those States vetoed with commendable promptitude. Some little time ago, in Kentucky, a member of the osteopathy brotherhood was charged with practising medicine within the meaning of the act of the State. He endeavored to escape from his unpleasant position by asserting that he was not practising medicine, but merely manipulating with his hands. Judge Thompson, however, took a different view of the case, and held that the manipulator, in his ignorance of the fundamental principles of medicine and surgery, had subjected the patient—a child suffering from hip disease—to much cruel and unnecessary pain, injuring his health and necessitating the employment of a qualified medical man. The court ruled that "any person who for compensation professes to apply any science which relates to the prevention, cure, or alleviation of the diseases of the human body, is practising medicine within the meaning of the statute." It would be well, and in the best interests of the medical profession and the general public, if this State were to follow the lead of Kentucky in her broad interpretation of the laws regulating the practice of medicine. Strenuous efforts should be put forth to nip in the bud this attempt to legalize the practice of osteopathy.

Perhaps it may be thought that, in thus enlarging on the probable dangers resulting to the medical profession from the competition of "osteopaths," we are making a mountain out of a mole hill. However, the fact that this bill is but the introduction of the thin edge of the wedge should not be overlooked. That such a bill should have been even introduced into the legislature of this State is a sufficiently serious matter, and if, through the apathy and indifference of the medical profession, by political influence, or by some unforeseen chance, it should become law, the Christian Scientists, faith healers, *et hoc omne genus*, would clamor to be placed on the same footing. It rests, therefore, with the medical practitioners of this State to protect both themselves and the public. *The Lancet* goes so far as to suggest that in England legislation should step in and prevent peculiar people, faith healers, from being allowed to murder their own children. The gullible public loves to be quacked, and that this is so readers of medical journals know well, as the subject is always being discussed in their columns. It is a question of the gravest import to the profession at large. Many of its members have already suffered, and unless efficient protective measures are quickly taken the security of all will be seriously threatened. The Medical Society of this State has already done excellent service in exposing and proceeding against charlatans. Since the law providing for the criminal prosecution of quacks was reenacted in 1895, this society has caused more than eighty persons to be arrested for practising illegally in the commonwealth. Thus we may leave with confidence in the hands of the legislative committees the task of rendering abortive the bill for legalizing the practice of osteopathy, and may rest assured that they will at any rate spare no efforts to bring about this desirable result. At the same time we would impress upon the minds of the medical men of this State the necessity of presenting a united front and of warmly resenting any intrusion on their privileges.

News of the Week.

The Medical Log of the Maine.—One of the first things recovered by the divers from the *Maine*, lying at the bottom of Havana harbor, was the journal of the medical officers. The package was under water four days. The blue-mark lines ruled on the paper at the government printing-office are nearly faded out, but the writing in the journal in the ink used by the navy is clear and distinct. Surgeon Heneberger, the *Maine's* medical officer, had brought the record up to the last moments before the wreck of the ship, the last entry being February 15th.

Shorter Hours for Drug Clerks.—At a hearing before the senate cities committee at Albany, strong opposition was expressed against Senator Ford's bill shortening the hours for drug clerks. Petitions were presented against the measure signed by many druggists and drug clerks. The bill was also opposed by the president of the board of pharmacy, the vice-president of the State Pharmacists' Association, the president of the Kings County Pharmacists' Association, the vice-president of the College of Pharmacy, and the president of the German Apothecaries' Association.

Mount Sinai Hospital.—A block of ground between Fifth and Madison avenues and One Hundredth and One Hundred and First streets was purchased some time ago by the board of directors of the Mt. Sinai Hospital, now at Sixty-sixth Street and Lexington Avenue, for the purpose of erecting a new building. It is purposed to begin work on a thoroughly modern hospital, to cost about $1,000,000, as soon as the architect's plans are completed. The cost of the ground upon which the new hospital will stand was $350,000.

Bequests in Dr. Seguin's Will.—The will of Dr. E. C. Seguin, which was recently filed for probate, leaves an oil painting of his father, Dr. Edward O. Seguin; a framed autograph letter, dated December 16, 1847, from Pope Pius IX., regarding his work for imbecile children; a bronze medallion of Charcot; and a large photograph of Brown-Séquard to the New York Academy of Medicine. He also gives the Academy of Medicine his collection of monographs and pamphlets on the nervous system, and all the other books in his library. All his instruments for the study of the nervous system and his books on the anatomy and physiology of the nervous system he leaves to the pathological laboratory of the Alumni Association of the College of Physicians and Surgeons.

The Late Dr. Lewis R. Hurlbutt.—Dr. W. G. Brownson, of Noroton Heights, Conn., sends us the following note on the death of Dr. L. R. Hurlbutt, of Stamford, Conn.: "The brief announcement of Dr. Hurlbutt's death was full of pathetic significance to

those best qualified to estimate the career of this scholarly, Christian gentleman. From the boyhood of Dr. Hurlbutt he was a devoted student of what is best in general, classical, and medical literature. As salutatorian in the Yale class of 1843, as tutor in mathematics and Greek, principal of Hopkins Grammar School, Hartford, his early record as a man of letters was no less brilliant than his subsequent work in the field of hospital and medical practice. For forty-five years he was an ornament to the medical profession. The *Daily Advocate* of Stamford compresses into a few truthful and comprehensive words his most fitting eulogy: 'He represented for years—so long that only the older inhabitants can remember their beginning—all that was most reputable and useful in the profession of medicine, most distinguished and respectable in social life, and most admirable in citizenship.' But few still in active practice can share with me the pleasant memories of Dr. Hurlbutt, extending back into the sixties. His prompt response when summoned, his cordial greeting, his sympathy, helpfulness, and support endeared him to his patrons; while his modest demeanor, steadfast friendship, courage, and loyalty to duty won the profound respect of his acquaintances and friends. The flourishing society of younger medical men, over whom for some years our Nestor presided, will miss his wise rulings and counsels, his dignified bearing, and unfailing courtesy. The public schools in which he was a familiar figure, the church which never looked in vain to him for counsel and support, and, above all, the large circle of personal friends and relatives to whom he was endeared—all have sustained a loss which time will not replace. The memory of such a personality is an inspiration."

The Late Dr. John G. Truax.—The following resolutions have been adopted by the medical board of the Harlem Hospital:

"*Whereas*, We, the members of the medical board of the Harlem Hospital, have learned with deep regret of the death of our late associate, Dr. John G. Truax;

"*Resolved*, That we record our recognition of the value of his services in the establishment, due largely to his untiring energy, of the Harlem Hospital, the organization of which was his work;

"*Resolved*, That we hereby desire to express our appreciation of his manliness and decision of character, his high sense of professional honor, and the zeal and ability shown by him in the practice of the profession which he loved;

"*Resolved*, That a copy of these resolutions be sent for publication to the MEDICAL RECORD, to the *New York Medical Journal*, to the *Journal of the American Medical Association*, and to the widow of Dr. Truax.

[Signed] "J. T. JOSEPH BIRD, M.D., *Secretary*."

State Aid for Johns Hopkins.—At the commemoration-day exercises of the Johns Hopkins University, Baltimore, on February 22d, President Gilman announced that, "in accordance with the wishes of many of its friends and supporters, taxpayers and citizens of Maryland, the Johns Hopkins University has determined to present a statement of its financial condition to the legislature of Maryland and to ask for State aid." The university was dependent in large measure upon the stock of the Baltimore and Ohio Railroad owned by it, and when the road went into the hands of a receiver the loss to the university amounted to $150,000 a year. Through guaranteed private subscriptions the university will receive $50,000 for five years, but it is still short $100,000 a year, and it is this sum that the State legislature is to be asked to make good.

The Medical Bills.—The amended health-board bill and the dispensary bill received the unanimous endorsement of the Medical Society of the County of New York at its recent meeting.

Pay for Accident Cases.—A writer in the *Public Ledger* of Philadelphia says that it is the custom at most of the hospitals in that city to pay with a drink the policemen directing accident cases to them, while another writer says that certain hospitals pay one or two dollars in cash for each patient so obtained. We wonder whether such a custom exists in New York?

Obituary Notes.—DR. A. RUSSELL STRACHAN, of this city, died on March 1st, at the St. Cloud Hotel, from injuries received while saving a woman and her child from being run over by a cable car. The woman and child were got out of the way, but Dr. Strachan was struck by the car and thrown some distance, falling heavily. It was thought at first that his injuries were slight, but serious symptoms developed, and he died about a week after the accident. Dr. Strachan was a graduate of Victoria College in Toronto in 1861, and was seventy years of age.—DR. JOHN YALE died in Beloit, Kan., on February 26th, at the age of seventy-eight years. He was born in New Hartford, Conn., and was a descendant of Eli Yale, the founder of Yale College. He was a graduate of the Yale Medical School in the class of 1841, and practised the greater part of his life in Ware, Mass.—DR. JOHN PARKER MAYNARD died at his home in Dedham, Mass., on February 26th, at the age of seventy-two years. He was a native of Boston, and was graduated from the Harvard Medical School in the class of 1848. While still a student, in 1847, he discovered the use of collodion in surgical dressings.—DR. THOMAS B. BAILEY, a passed assistant surgeon in the United States navy, was found dead in his apartments in Washington on February 24th. A note was found saying that he was suffering from a disease of the heart and that he had become convinced that he could never be cured. He thought it best, therefore, to end his life by means of cocaine without further suffering. Dr. Bailey was thirty-four years old, and was appointed to the navy from New York in 1889, and was made passed assistant surgeon in 1892. He had lately been on the China station, but was recently ordered home and assigned to duty at the Washington navy yard.—DR. WILLIAM C. HOLMES, of Waterbury, Conn., died on February 22d, at the age of forty-three years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1880.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 17, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

Report of Committee on National Public Health.—The committee embodied in its report the following resolution, which was unanimously adopted:

"*Resolved*, That the fellows of the New York Academy of Medicine do earnestly recommend the establishment of a bureau of health, with the power to administer, within constitutional limits, the sanitary needs of the United States."

DR. M. ALLEN STARR, speaking for the committee in regard to the two bills bearing on this subject, stated that, in the opinion of the committee, the passage of the Caffrey bill would be a misfortune to the country, not only because it would postpone the establishment of a national bureau of health, but because it unduly emphasized the importance of the seaports in connection with sanitation. On the other hand, the Spooner bill was substantially the bill advocated by the Academy of Medicine before Congress one year ago. The following resolution was adopted:

"*Resolved*, That the fellows of the New York Academy of Medicine give their unqualified support to the Spooner bill."

Report of Committee on Medical Expert Testimony.—In reporting progress, this committee stated that it had been determined that improvement in the system of medical expert testimony must proceed along three lines, viz.: (1) the establishment of some standard of excellence for experts; (2) the appointment of the experts for a given case by the presiding judge; and (3) the fixing of the fees by the court, and the deposit of a certain portion of the sum in advance. It was recommended that those registering as experts before the board of regents should be required to specify the particular branch of medicine, that they should have been in practice ten years and in the practice of their specialty for five years, that evidence of special study should be presented, together with a certificate of good moral character, and indorsements by the local county medical organization and a judge of a court of record.

Non-Tuberculous Inflammation of the Spine; Syphilitic, Rheumatic, Malignant, Gonorrhœal, Typhoid, Infectious, Traumatic.—DR. T. HALSTED MYERS read a paper with this title, the meeting being in charge of the section on orthopædic surgery.

Syphilitic: He said that syphilitic lesions of the vertebræ presented special difficulties in diagnosis. The relation of congenital syphilis to tuberculosis was not yet well understood, although the general opinion seemed to be that the syphilitic infant constituted a favorable soil for tuberculous infection. The cervical region was the one most commonly affected, possibly, as some have claimed, because of its proximity to the throat and pharynx, where syphilitic lesions were so frequently located.

Rheumatic: Of this group by far the most common was rheumatoid arthritis, which affected the bone as well as the other joint structures. It was never accompanied by suppuration. It was a chronic progressive disease, not yielding to treatment. The ribs were often involved. The cervical region of the spine was usually the last to be affected. The pain was very variable in degree, and was often the least when there was the least mobility. Dr. Myers said that he had had no experience with the so-called Paget's disease. It occurred late in life, and was a progressive, rarefying osteitis. The normal spinal curves became exaggerated as the disease advanced.

Malignant: This form of disease of the vertebræ was quite rare. Carcinoma and sarcoma occurred with about equal frequency, and both might be primary, but they were usually secondary. When a primary malignant growth was recognized, the occurrence of spinal symptoms would, of course, be traced to their proper source, but under other circumstances the diagnosis was not easily made. Kyphosis was seen in only nine out of twenty-nine cases in a series that had been reported. It usually occurred after the age of forty-five years. The cachexia at times did not appear until late. The spinal nerves were often involved in the new growth. Such cases were often mistaken for sciatica, lumbago, or Pott's disease. Hydatids sometimes attacked the spine, as in a case reported by Dr. Lloyd.

Gonorrhœal: This affection of the spine was exceedingly rare. In a series of one hundred and nineteen cases of gonorrhœal rheumatism reported, the spine was not involved in any of them, and of another series of over one hundred cases in only two was the spine affected.

Typhoid: This process was supposed to be an inflammation of the fibrous structures of the spine. It was associated with acute pain, with little or no rise of temperature. The attack usually came on shortly after the subsidence of the typhoid fever, and recovery might be rapid or might be delayed many months. The profession was greatly indebted to Dr. Gibney for its knowledge of this affection. According to Professor Welch, months and years after typhoid fever osteomyelitis might develop.

Infectious: This heading included those inflammations following scarlet fever, measles, and similar diseases. The germs usually attacked the cervical spine, probably from direct transmission from the throat. The generally healthy appearance of the patient, the mode of onset, and the rapid improvement were the chief points in the diagnosis.

Traumatic: Under this head were included those traumatisms of the spine which simulated Pott's disease. When the vertebræ were fractured, little or no injury was done to the cord; there were local weakness and some tenderness, but often no crepitus and very little pain. It was difficult to keep these parts quiet, so that it was probable that union did not take place, and, as a result, the weight of the body gradually produced kyphosis or lordosis. Personally, he did not believe that tuberculosis occurred primarily in the osseous system.

Conclusions.—(1) Syphilitic treatment should be pushed when there was a possibility of this disease being present; (2) fractures should be more carefully protected, and for a longer period, to prevent deformity and paralysis, and to relieve pain and disability; (3) rheumatoid arthritis could be rendered less deforming and less dangerous to life by securing ankylosis in good position, if ankylosis could not be avoided; (4) from a medico-legal standpoint it was important to remember that not all chronic cases of spinal disease were tuberculous; (5) life insurance should not be refused in these cases on any hard-and-fast rule, but they should be judged on their individual merits.

DR. C. C. RANSOM said that in speaking of rheumatic and gouty disease of the spine it was customary to include rheumatoid arthritis, but the latter was so different that it should be considered separately from affections of the spine. In nearly one thousand cases of rheumatism and gout treated at Richfield Springs, he had notes of only three or four in which the intervertebral joints were alone involved. The disease was usually of the chronic type, but differed in no way from rheumatism of the other joints. The tender-

ness in true arthritic cases was elicited only on deep pressure and on movement. In the muscular type the tenderness would much more rapidly disappear under prolonged movement than in the cases in which the spine itself was involved. It was only in exceptional cases and in persons of advanced years that fibrous ankylosis occurred. In differentiating rheumatism of the spine from muscular rheumatism, the chronicity of the trouble, the affection of other joints, and the deep-seated tenderness would usually suffice to make the diagnosis. It was distinguished from rheumatoid arthritis by the absence of deposit about the articulation, together with the characteristic deformities of the other affected joints in the latter disease, and also by the accompanying muscular atrophy. It was differentiated from spinal caries by the absence of tenderness on vertical pressure, as in the jarring of walking. To cure the trouble dependence must be placed on general tonic treatment, including hydrotherapy. Local douches of alternately hot and cold water would be found of the greatest service, and massage was always indicated. Among the drugs, iron and arsenic were the most useful. In the diet of these cases, every individual was a law unto himself. Rheumatoid arthritis affecting the spine was much more frequent and more serious because of its tendency to produce deformity and its irresponsiveness to treatment. As a rule, it was insidious in its onset. The upper cervical and the lumbar regions were those most usually affected, though the whole spine might be involved. There were always accompanying structural changes in the joints. The treatment should aim to check the disease as far as possible. Iodide of potassium, iron, strychnine, and the hypophosphites were the drugs chiefly of use, and the diet should be most nutritious.

Dr. V. P. Gibney said that in malignant disease of the vertebræ the early symptoms were often puzzling, yet it was quite possible to make the diagnosis during life. The intensity of the pain and its localization in certain regions were important aids to the diagnosis. In the case of women, it would often be found that the carcinomatous disease of the vertebræ was secondary to carcinoma elsewhere, usually in the breast. The measures which usually give relief in cases of tuberculous disease of the spine utterly failed in malignant disease of the spine.

Irritable Spine.—Referring to the common condition described as "spinal irritation," Dr. Gibney said that in quite a number of these cases he had known the treatment for Pott's disease to be insisted upon because of the irregularity of the spinous processes. It should be remembered that in Pott's disease, particularly in children, there was very rarely tenderness over the spinous processes. This served as an easy means of differentiating this disease from an irritable spine.

Dr. W. R. Townsend said regarding the rarity of these affections, as compared with tuberculosis of the spine, that his experience at the Hospital for Ruptured and Crippled led him to believe that the proportion of syphilitic cases was only about three or four in a thousand. It was not sufficient in making the diagnosis of syphilitic disease of the spine to rely upon the presence of a dactylitis, for in some instances it was practically impossible to distinguish between a tuberculous and a syphilitic dactylitis. In rheumatic disease of the spine it would be found that the kyphos was more rounded and less distinct than in tuberculosis of the spine. He had never seen a case of gonorrhœal inflammation of the spine.

Dr. S. Lloyd said that another class of cases which might be confounded with tuberculosis of the spine was those in which there had been a tearing of the spinal ligaments, particularly of the ligamentum subflavum, with hemorrhage and subsequent inflammation of the spine. Some years ago he had seen a healthy, non-tuberculous child, who had injured the spine. Gradually the case had presented the picture of a tuberculous spine. Finally she was operated upon and an ordinary non-tuberculous abscess found, and the pus and blood-clots were evacuated. The child eventually recovered. In a second class of cases there was hemorrhage into the spinal column following injury, particularly after a sudden and forcible bending, as from a weight bending down the head. A third traumatic class was those in which there were a partial dislocation of the spine, and the immediate appearance of a kyphos and hemorrhage. A fourth class was made up of fractures, particularly incomplete ones, which very often went unrecognized. In these cases, owing to the fact that a certain time was required for the development of a callus, the paralysis did not supervene immediately after the injury.

Hydatids of the Spine.—Dr. Lloyd referred to his case of hydatids of the spine. He said that at first there had been a distinct kyphosis, and the patient had been treated by a number of prominent surgeons for tuberculous disease of the spine. He finally developed an apparently marked curvature of the upper part of the spinal column. It was not until the development of a tumor that the true cause of his curvature was recognized. After the removal of this, his symptoms disappeared, and he returned home and went to work. Some months afterward he was injured in a railroad accident, his spinal column being crushed. This caused his death. The autopsy showed the part operated upon to be free from hydatids, but two small hydatid cysts were found in the cauda equina.

Scurvy, Rickets, and Aneurism.—Dr. R. H. Sayre thought that the occurrence of antero-posterior curvature in small children, associated with rickets and scurvy, should not be overlooked. He had seen many tuberculous and rickety children with marked antero-posterior curvature of the spine, and tenderness, and with many of the symptoms of Pott's disease. We should also bear in mind the possibility of erosion from aneurism being confounded with Pott's disease. He had seen cases of this kind in which a marked kyphos had been produced as a result of the destructive effects of the aneurism. In one or two recorded instances the true condition had not been recognized, and the attempt to suspend the patient had resulted in rupture of the aneurism and death. He only recalled seeing one case of inflammation of the spine which he regarded as gonorrhœal. There were decided pain and disability of the spine in this case, with very slight kyphos, but there was a definite history of gonorrhœa. He had seen one or two curious neurotic spines in which the exact diagnosis had not been very clear to him. In one of these there were marked limitation of motion in the neck and decided pain. The application of a support relieved the pain, but after a while nearly the entire spine became involved in the disease, and it was almost absolutely rigid from one end to the other. The stiffness even involved the articulations of the ribs and other joints in the body. He had watched the case a number of years, and had observed decided improvement under the persistent use of massage. There was no history of tuberculosis or syphilis, and it had not been benefited by anti-syphilitic treatment.

A Case of Malignant Disease of the Spine.—Dr. B. Farquhar Curtis said he desired to put on record a case of malignant disease of the spine secondary to a tumor of the breast. The patient was a woman, thirty-five years of age, who had been admitted to the medical wards of St. Luke's Hospital, November 7, 1893. The right breast had been amputated one year before for a malignant tumor. Five months before admission she began to have pain in the back

and right side of the chest. On examination, all the organs seemed normal, and there was no local recurrence in the breast. There were some pain and stiffness in the left shoulder and over the three lower intercostal spaces on the left side. On November 15th there was marked anæsthesia of the forearm, pharynx, and conjunctiva, and the knee reflex was increased. The next day it was noted that the knee reflex had disappeared, and that sensation and motion were absent below the umbilicus, and that there was loss of control over the rectum and bladder. A kyphosis was discovered in the mid-dorsal region. The paralysis was absolute, and the pain was so severe that he had been induced to do a laminectomy. The cord was found to be slightly congested at the point of the kyphosis. The bone at the sixth dorsal vertebra was softened and projected somewhat on the anterior surface of the spinal canal; there was, however, no marked thinning of the cord at that point. The removal of the laminæ did not relieve the pressure at all, and the symptoms continued. The wound healed by primary union. Quite early in the history of the case a large bedsore had developed on the sacrum. The patient died sixteen days after the operation. It was worthy of note that in this case, before the development of the kyphosis, the chief symptom was the pain, and this was not very intense. In these cases, to establish the diagnosis a most searching and thorough examination was required.

Dr. George R. Elliott spoke of the medico-legal aspect of neurotic affections of the spine, and the importance of carefully observing and noting all the organic findings.

Dr. C. N. Dowd said that mention had been made of the frequency with which the spine is involved secondarily by malignant disease. Last fall he had presented to the surgical section the histories of twenty-nine cases of cancer of the breast, in five of which there had been distinct symptoms of carcinomatous involvement of the spine. They had not been proved by autopsy, but the clinical symptoms seemed to be clear and definite.

Dr. A. B. Judson said that a review of the symptoms of non-tuberculous inflammation of the spine showed that, as a rule, spinal pain and spinal disability, which were so often absent in Pott's disease, were present in non-tuberculous inflammations of the spine. It was strange that when the spinal column had been virtually broken there was an absence of spinal pain and disability. Again, in non-tuberculous inflammation, the onset was comparatively frank and alarming, which was in marked contrast to the insidious approach of tuberculous disease of the spine.

Mercury may Improve Tuberculous Lesions of the Skin.—Dr. B. Laposki said that the text-books contain classical descriptions of the differential diagnosis of syphilitic and tuberculous dactylitis, but in practice it was often difficult, if not impossible, to make the distinction. A number of cases had been reported on excellent authority, in which tuberculous lesions of the skin had been distinctly improved by the use of mercury.

Difficulties in the Diagnosis.—Dr. Edward G. Janeway said that he had seen a number of cases of carcinoma of the spine, mostly secondary. They were quite commonly observed after the removal of malignant disease from the breast. Protracted pain in the spinal column, resisting treatment, might usually be ascribed to a new growth, aneurism or inflammatory disease. He recalled the case of a boy, who after being kicked, developed a secondary inflammation of the spine, which had been thought during life to be a cerebro-spinal meningitis. The autopsy showed inflammation in the interior of the sacrum and necrosis, and the inflammatory process could be traced up the spine. He had seen several cases which had been lectured upon as examples of tuberculous disease of the spine, and which had proved to be really cases of aneurism involving the spine. Sometimes it was very difficult to make the diagnosis, as, for instance, in a case in which there was a history of injury, tuberculosis, and syphilis. It was not uncommon to find tuberculosis in a person who had had syphilis, and there was no reason why a tuberculous person should not have a syphilitic spine. Then there were certain cases, best designated as "tertiary syphilitic fever," which were sometimes mistaken for tuberculosis of the spine by very eminent diagnosticians, and yet which yielded readily to antisyphilitic treatment. In his experience, it was exceptional not to have severe pain in malignant disease of the spine.

Dr. Myers closed the discussion. He said that in the cases in which he had spoken of the existence of a dactylitis as an indication of syphilis there had been, in addition, a clear history of syphilis. In the cases of malignant disease of the spine that he had seen, the pain had been severe up to the occurrence of the paraplegia.

SECTION ON SURGERY.

Stated Meeting, February 14, 1898.

W. W. Van Arsdale, M.D., Chairman.

Resection of Sigmoid Flexure for Carcinoma.—Dr. James P. Tuttle presented a man on whom he had performed this operation. The patient had been treated by several physicians, who had told him that he was suffering from chronic constipation merely. On examination with a Kelly tube, the speaker had been able to detect a carcinoma, situated about eleven inches up the bowel. After the carcinomatous portion of the bowel was taken out, it was found that there was no peritoneal covering, and the affection was too deep down to admit of an end-to-end suture. It had, therefore, occurred to him to sew up the upper divided end of the rectum entirely, and then make an incision in the anterior wall of the rectum, where it was covered with peritoneum. Through this the remaining portion of the colon was dragged, and held in place by sutures on the outside, but not passed through the bowel. This acted well at first, but the man soon developed a very bad stricture, due to contraction at the point of union. To remedy this Dr. Tuttle had adopted the plan of Dr. Bacon, of Chicago, viz., the application of long forceps to the obstructing portion, one blade being in the rectum and the other in the colon. The parts were firmly adherent by the time the forceps had cut through these tissues, and a good opening was left. Later it was found that a little portion of tissue, like a polypus, hung down and caused some obstruction. Through a Kelly tube a Bosworth snare was introduced and the polypus snared off, with good result.

Dr. John B. Walker said that in a recent similar case, an end-to-end anastomosis being impossible, he had closed the lower end of the rectum, and made an end-to-side anastomosis. It was too early yet to say whether or not there would be contraction in this case also.

Dr. Frederick Kammerer said it had been his experience that in resections and end-to-end anastomoses of the rectum and sigmoid flexure stenosis was very likely to occur—indeed, it seemed to him that after six or eight months there was invariably decided contraction. In the cases in which he had made the end-to-side anastomosis with Murphy's button, he had not observed this. In one case, examined many months later, he had been able to prove that not the slightest contraction had taken place. This might be

due to the fact that with the Murphy button the point of contact was very small, whereas with use of sutures this area was quite large. The method with the Murphy button seemed to him the ideal one of approximating cut surfaces of the intestine in end-to-side anastomoses. The method adopted by Dr. Tuttle was very ingenious as well as effective. It was important to avoid suturing the part of the bowel not protected by peritoneum.

Inoculation Tuberculosis.—Dr. Martin W. Ware presented an infant of nine months, born of healthy parents. There was no history of tuberculosis in the parents. When it was a few days old a midwife pierced the ears of this baby. This was followed by ulcers which did not heal readily. When the speaker had first seen the child, a few months ago, there had been small miliary abscesses in the course of a lymphangitis, starting from the site of the puncture. At present there was a large number of tuberculous glands, and this process seemed to have extended along the clavicle into the axilla. The case was unique as far as the method of infection was concerned. The clinical features were quite characteristic at the present time.

Fracture of Patella; Plastic Operation on the Quadriceps.—Dr. John F. Erdmann presented a man who, in October, 1896, slipped and fell, sustaining a transverse fracture of the patella. It was wired within two weeks after the accident, and after six weeks he was allowed to go out. About ten days afterward he again slipped and fractured the patella. It was again wired, and he went out after a number of weeks. Two or three weeks later he returned with a third fracture of that patella. Dr. Erdmann had seen him a few months after this fracture. At this time there was a large interval between the fragments, and one fragment was firmly adherent to the condyles of the femur. At the request of the patient he had operated, cutting off all the attachments of the vastus externus and internus, and of the lateral ligaments, and excising a V-shaped portion of the quadriceps. This enabled him to bring the posterior surfaces of the fragments thoroughly together, but the anterior surfaces were separated about one-eighth of an inch. The limb was hyperextended and put up in plaster-of-Paris, the patella being sutured with very heavy wire, and the section of quadriceps tendon with silkworm gut. The operation was done on October 6, 1897, and there had been no trouble since then from the suture. The man was kept in hospital about ten weeks. During this time he developed a peculiar range of temperature, without the slightest evidence of purulent formation. During the daytime the temperature was normal, but it rose quite high about 1 A.M. He was finally discharged from the hospital with a good functional result, and with the fragments absolutely in contact.

Fracture of Patella Treated by Massage.—Dr. George Woolsey presented a man to show the good result of this comparatively new method of treatment. The patient, a cab driver, forty-seven years of age, had fractured the patella on January 2d, and had been admitted to Bellevue Hospital on the following day. The left knee was swollen and painful, and there was crepitus between the lower and upper fragments. For two days the limb had been kept in a posterior splint and cold compresses applied, and then massage with passive motion had been used daily. On January 8th, or six days after the injury, the patient was able to lift the leg off the bed. Four days later he was allowed up with a light bandage about the knee. Twenty-four days after the injury, at his own request but against advice, he went home, returning several times for massage. At present he was able to bend his knee beyond a right angle, to straighten it, and to walk without crutch or cane. The case, it should be said, was a favorable one, as there had been no evidence of contusion over the knee. The separation was very moderate—only about half an inch. This was the quickest result that he had secured from massage. While he would not say that there was bony union, it was evident that the union, if fibrous, was very firm.

Dr. Woolsey thought the case presented by Dr. Erdmann a very successful one, and the procedure very ingenious. At present he had a man under observation who had had three fractures of the patella, two of which had united without operation. The last refracture had occurred two or three weeks ago, and had resulted in a tearing away of the fibrous union from the lower or smaller fragment. On operating he had found that this lower fragment was atrophied as well as small. No periosteal covering remained, and it was only after the division of the quadriceps that the fragment could be brought well together.

Dr. J. B. Walker said that some time ago he had had a case of fracture of the patella sutured with kangaroo tendon. The patient did well for ten days, and then had a chill and an elevation of temperature. On examination of the wound no evidence of sepsis was found. The patient then stated that he had had malaria previously. A few days of treatment with quinine dispelled all the unpleasant symptoms. On mentioning this case to Dr. Bloodgood, of Baltimore, the speaker had learned that in the Johns Hopkins Hospital there had been several cases in which after operations there had been chill and fever, and examination of the blood had shown the presence of the malarial plasmodium.

Dr. W. W. Van Arsdale thought that at present apparently just as good results were obtained from massage as from wiring, but the massage cases had not been kept under observation as yet for a sufficient length of time. That the fracture recurred after both methods of treatment could not be denied. In cases of long standing in which there was difficulty in approximating the two ends, he had known good surgeons to refuse to operate; hence the method brought out by Dr. Erdmann, of making a V-shaped incision in the tendon, without cutting through the quadriceps entirely, seemed to him a useful as well as a unique procedure. The remarks of Dr. Walker led him to say that frequently in the Mount Sinai Hospital they had noticed high temperature after operations for fracture of the patella—even as high as 105° F.—and yet there was no trouble in the joint, and the result was an excellent one. He, therefore, thought the surgeon should take courage and not needlessly interfere with the dressings under such circumstances.

Dr. Irving S. Haynes asked if massage had been used in the bad cases in which there were much swelling, separation of fragments, and laceration of the capsule—in short, in the cases in which there was evidence that a periosteal flap had fallen between the fragments.

Dr. Robert T. Morris said that in all the cases in which he had operated he had found the inversion of a large hood of periosteum, and this had been quite adherent. In most instances also he had found a firmly organized blood clot. Usually the lower fragment faced away from the upper fragment, thus offering another mechanical obstacle to bony union.

Dr. Erdmann remarked that four years ago in a case of multiple fracture of the patella he had encountered an unusually long and thick piece of tendon which was firmly wound around the fragments. In the case he had mentioned, in which there had been such a peculiar range of temperature, this was probably due to some personal idiosyncrasy, as it had not been influenced by quinine but had subsided under morphine.

Dr. Woolsey said that he had treated by massage such cases as Dr. Haynes had asked about, but without expectation of securing bony union. In his opinion the tilting of the fragment was due to the quantity of effusion and the presence of blood clots. The object of the massage treatment was to reduce these two factors. In certain cases it was possible and easy to get a good functional result even under such circumstances.

Dr. George G. Hopkins said that the pathology of fracture of the patella showed that half or three-quarters of an inch of tissue was necessarily thrown down between the two fragments. He had never seen a fracture which had not been wired in which ligamentous union with considerable separation had not occurred.

Dr. Van Arsdale remarked that the originators of the method of treating fracture of the patella by massage insisted that when there was much swelling there should first be puncture and evacuation of the effused blood.

Amputation of Arm for Evulsion of Forearm.—Dr. Erdmann then presented a man upon whom he had performed amputation of the arm for evulsion of the forearm. There had been a complete rupture of the pectoralis major muscle, so that there was an interval between the external and internal portions of this muscle into which the fist could be placed. There had been complete restoration of the function of the pectoral muscle.

Secondary Suture of Median and Ulnar Nerves.—Dr. John Roger exhibited a young man who had had the palm and the anterior surface of the forearm lacerated by a cogwheel. Both the median and ulnar nerves had been divided, but this had not been noticed by the physician first in attendance until the patient had severely burned his hand by placing it in very hot water. When the operation for secondary suture of these nerves was undertaken, it was found that their divided ends were separated about half an inch. The distribution of these nerves to the hand was well shown by the boundaries of the areas of anæsthesia.

Appendicitis; Fecal Fistula; Resection of Intestine.—Dr. Richard P. Francis reported the following case: A boy, aged fourteen years, had enjoyed good health except for frequent attacks of indigestion. In the spring of 1897 one of these attacks had been sufficiently severe to keep him in the house, but after that he had been in apparently perfect health up to October 19, 1897. At this time he was seized with general abdominal pain accompanied by nausea, and when he was seen the next afternoon by Dr. Francis there were pain and tenderness all over the abdomen, more marked in the right iliac fossa, and his temperature was 99° F. The next morning the pain was more severe in the left iliac region, but the other signs were unchanged. Nevertheless the patient appeared to be seriously ill. A diagnosis was made of probable perforative appendicitis and septic peritonitis. He was accordingly removed to the Mountain Side Hospital at Orange, and operated upon. The appendix was found lying over the brim of the pelvis. The wound healed steadily by granulation until two weeks after operation, when a swelling to the left of the umbilicus announced the development of a secondary pelvic abscess. This being incised, a quantity of foul pus was evacuated and a small spot of gangrene was discovered on one coil of intestine. The next day pus and fæcal matter were discharged into the wound. Neither flatus nor fæces were passed by the rectum, and the patient's general condition steadily failed. Dr. McBurney then saw the case in consultation, and advised against operation, on account of the bad general condition and the possibility of sustaining the patient by proper nourishment for a time. The wisdom of this advice was proved by the subsequent history. Fæcal matter was discharged from the bowel the next day, and the patient steadily improved after this time. At the time he left the hospital, on December 17th, a probe could be readily passed into the two openings in the bowel, and he had daily evacuations through the rectum. By January 1st, the fistula had contracted to the size of a lead pencil. On January 6th there was a sudden attack of vomiting with moderate abdominal pain. An enema produced a large normal fæcal movement. Subsequently nearly a pint of shreddy mucus was discharged from the rectum. On the fourth day there was more vomiting. There had been no discharge through the fæcal fistula since the beginning of the attack. He was readmitted to the hospital, and on January 10th, through a median incision, the colon was seen to be collapsed. The incision was extended in both directions freely, and the scar and knuckle of intestine were included in two elliptical incisions. Several other knuckles of bowel were also found to be adherent to each other and to the abdominal wall. The obstruction was evidently not due to the cicatricial contraction of this portion containing the two openings. This part of the bowel, for a distance of three or four inches, was excised, and an end-to-end anastomosis made. The operation was necessarily a very tedious one, and at its close the patient was in profound shock. Four or five hours afterward there was a fluid evacuation from the bowels. He was kept on a milk diet until the button was passed on the twelfth day. Three weeks from the day of the operation the patient left the hospital well.

Dr. Kammerer said that while he believed that perhaps the majority of the cases of fæcal fistula following appendicitis could be healed in the way described, and while, of course, freeing the intestine from its surroundings should always be tried, this method would occasionally fail, owing to the adhesions, the consecutive changes in the intestinal walls, and the impossibility of separating them sufficiently.

Dr. Morris thought that occasionally valuable time might be lost in trying to save portions of bowel that were not of much importance. It was often well to bring together the free ends of the bowel above and below the mass of dense adhesions, and then strip them out.

X-Ray Burn; Amputation of the Thigh.—Dr. J. P. Tuttle reported a case in which amputation of the thigh had been demanded after an *x*-ray burn. The man had been injured in the war. Dr. Tuttle and Dr. McBurney had together removed a floating cartilage from the knee-joint about four years ago, and, although the operation had been largely an experimental one, it had given the man relief from pain for three years. His sufferings had then returned. Accordingly, last September, the joint had been examined with the *x*-rays, the examination lasting over one hour. There was no pain at the time, but three weeks afterward the parts began to turn red, and in two days all of the skin about the joint, except on the posterior and internal surfaces, sloughed away. Portions of the surface healed and again broke down. Then skin was transplanted from two different individuals, and the first attempts in this direction proved so successful that the remainder of the surface was covered over in like manner. But at the end of five weeks both of these areas of skin grafting broke down. When the man came under Dr. Tuttle's observation three weeks ago, an area measuring six and one-half by five and one-half inches presented the typical features of an *x*-ray burn. In consultation with Dr. E. B. Bronson and Dr. V. P. Gibney, it was decided to try the effect of constant irrigation with carbolic-acid solution. Only for the first two or three days did this seem to act well; then the surface became more unhealthy. As the man's health was failing rapidly, and he was becoming addicted to morphine, a consul-

tation was held, and it was decided that the limb should be amputated. This was done on February 8th, and so far the patient had done well. The specimen was interesting as showing that the pathological condition found in the burned area extended down even to the capsular ligament.

Very Different from a Burn.—Dr. E. B. Bronson said he thought the term *x*-ray burn a misnomer, for the whole history of these cases pointed to a process entirely different from a burn. Instead of beginning from without it began within, and was reflected to the skin. The fact that these injuries did not make their appearance immediately after the exposure to the *x*-rays seemed to show that the condition was not comparable to an ordinary burn. Often two or three weeks elapsed before there was the slightest reaction. Sooner or later in these cases of so-called *x*-ray burn, a gangrenous process made its appearance, and was the outward manifestation of some inward process, probably connected with the nervous system. This gangrenous process was peculiar, in that the slough looked like chamois leather, and that it was associated with intense capillary congestion of the papillary layer. The specimen presented was an excellent exemplification of the statement that this process was by no means confined to the skin. In connection with the management of these very trying cases it was interesting to recall the fact that Dr. Seneca D. Powell claimed to have achieved better success from excision of the skin in the affected area than by the usual methods.

Dr. William Vissman said that sections from the centre of the specimen presented showed a mass of connective tissue, with the walls of the blood-vessels infiltrated with round cells. This extended up on to the intima of the popliteal artery. There seemed to be a gangrenous process, possibly due to an arteritis of some of the smaller blood-vessels. He had not yet had an opportunity to examine the whole specimen thoroughly. Whatever the process that had existed in the bone, it seemed to have passed from within outward.

Dr. V. P. Gibney said that he had known this patient for many years, and from an experience with one case of *x*-ray burn, which had healed only after eighteen months, he had felt satisfied that the only thing to do for this man was to amputate.

Dr. Van Arsdale asked if there was anything in the statement that had been made, that coating the part with vaseline before exposing it to the *x*-rays would prevent such unfortunate consequences.

More Liable to Occur with Induction-Coil Apparatus.—Dr. J. P. Tuttle said it had been stated that no such *x*-ray burn had been caused when the static machine had been used to generate the *x*-rays, and that it had always been observed in connection with the use of the Ruhmkorff-coil apparatus. It was worthy of note that in his patient the applications which ordinarily relieve the pain of burns seemed only to aggravate the man's sufferings. It had been suggested that thin pieces of aluminum should be placed over the part to guard against these burns.

Their Chronicity.—Very few of these injuries healed in less than nine months. Dr. Powell had told him that he had cut out several of these, and they had healed in six or eight weeks. Apostoli had tried this method of dissection in his case. It had healed up but broke down again subsequently. Dr. Tuttle said that he knew personally of three of these cases. One occurring eighteen months ago was now getting well; one of twelve months' standing had only been slightly reduced in size by grafting and all sorts of treatment; the third one occurred six months ago, and was now in practically the same condition as at first.

Intestinal Parasites in the Tip of the Appendix.—Dr. George Woolsey reported a case of appendicitis, in which the appendix had been removed last July from a girl, aged twelve years, operated upon in the interval after the second attack. The first attack had occurred in November, 1896, and the second in June, 1897. The tip of the appendix was found to contain some intestinal worms, apparently the ordinary pinworm, or oxyuris vermicularis. He had been unable to find any reference in the literature to such intestinal parasites as an exciting cause of appendicitis.

Dr. R. T. Morris said that he had reported two cases of this kind, and had seen one other. In still another, the appendix contained large round worms instead of the oxyuris. In all of these cases erosion of the mucosa had been the principal feature. The subsequent changes from infection were not so marked as after injury to the appendix. These worms by their presence seemed to cause a slow ulceration. He thought at least ten or twelve cases had been reported in which entozoa had been found in the appendix, but they had been recorded under an improper title, and hence had usually escaped notice.

Appendicitis and Localized Tuberculous Peritonitis.—Dr. Woolsey also reported a case of a man, twenty-five years of age, who had had a pulmonary hemorrhage two years before, and whose mother had died of phthisis. He had lost some flesh recently, but had been in fair health. The symptoms of appendicitis had developed suddenly, but had not been very acute. The operation was done on January 24th, and the incision opened into a small cavity containing a drop or two of purulent fluid. The tumor consisted of a greatly thickened appendix bent on itself, and in the concavity of the bend was the pocket which had been opened. The omentum was adherent to its surface. The omentum over the mesentery of the appendix and the lower end of the colon was studded with what appeared to be miliary tubercles. Some years ago he had seen a case in which a tuberculous appendix had been the starting-point of a large tuberculous abscess. He had been inclined to believe that in the case just reported the appendix had been the starting-point of a tuberculous peritonitis, but the pathologist's examination of the appendix did not appear to bear out this view.

Hypertrophied Kidney; Nephrectomy.—Dr. George G. Hopkins presented an enlarged kidney removed by operation from a patient who had been referred to him by Dr. Hewlitt, of Babylon. Five years ago the man had first experienced occasional pain in his right side, and at these times the urine had contained pus. During the past year these attacks had become more severe, and had recurred sometimes as often as three times in a month. They came without warning, and the pain was exceedingly severe. He had removed the kidney on November 3d, by the lumbar incision parallel to the twelfth rib. The kidney was so large that it had been necessary to make a perpendicular incision also. On removal it weighed thirteen and one-half ounces. The attachments were very short, so that the ligation of the vessels was difficult. The pelvis of the kidney was dilated and the organ hypertrophied, probably as a result of stricture of the ureter. Since the operation there had been no pus in the urine, and only one attack of pain. The man was again at his work.

Skiagraphs of Coxa Vara.—Dr. Willy Meyer exhibited skiagraphs of the femora of a healthy young man of seventeen years, a photographer. His occupation was not such as to predispose to a bending of the neck of the femur. He had pain in the right hip-joint, but the motions of the joint were all normal, save for a slight impairment of abduction. There was shortening of half an inch, due to a diminished length of the femur. The skiagraphs showed that the trochanter on the right side was decidedly turned forward.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 26, 1898.

T. Mitchell Prudden, M.D., President.

A Modification of Cullen's Method of Preparing Fresh Sections for Microscopic Work.—Dr. Eugene Hodenpyl read this paper. He said:

"It is frequently desirable at surgical operations, at autopsies, or in general laboratory work, to obtain quickly stained sections for diagnostic purposes. Fresh unstained sections, while they are valuable for the study of certain lesions, are open to so many serious objections that they cannot be made use of for the purposes indicated. Moreover, fresh sections cannot be satisfactorily stained unless they have been previously fixed or hardened by some preservative. Of the various hardening-agents which have been tried for rapid fixation of frozen sections, none had been found successful until Cullen ('Beschleunigtes Verfahren zur Färbung frischer Gewebe mittelst Formalins,' *Centralblatt für allgemeine Pathologie*, 1895, Bd. No. 11, pp. 448-450; also *Johns Hopkins Hospital Bulletin*, April, 1895, and May, 1897) suggested the use of formalin either before or after cutting, as a partial fixative, when fairly successful results were obtained.

"A serious objection to the use of this method I have found to be the shrinkage and consequent distortion which always occur to a greater or less extent. At times so great a shrinkage took place in my sections that they were entirely useless. At Dr. Prudden's suggestion, I have devised a scheme of fixing sections on cover glasses by means of albumen. This may be accomplished by impregnating sections with a solution of egg albumen, floating them on cover glasses, and finally coagulating the albumen. By this means shrinkage and distortion, which would otherwise occur from the subsequent action of alcohol, may be largely if not entirely prevented.

"This modification does not materially increase the time required to prepare stained fresh sections for the microscope. I have repeatedly cut sections of fresh tissues, fixed them on cover glasses, and have hardened, stained, and mounted them in as short a time as nine minutes. Furthermore, it permits the use of hardening-agents other than formalin. Fair results have been obtained with osmic acid, mercuric chloride, etc. For purposes already indicated this modified method seems to be a valuable one, since it enables one to determine the nature of new growths, or the lesions of viscera, etc., within a few minutes—a procedure which would otherwise require hours or days to accomplish by the ordinary hardening and impregnating methods. Cullen's method, as may be imagined, is not applicable for all tissues. The results obtained by the suggested modification have been entirely satisfactory for diagnostic work, but for fine structural details other methods are still to be preferred.

"The technique of the method is as follows:

"1. Almost any form of freezing-microtome may be used. The freezing-agent may be ether, carbonic acid, or rhigolene.

"2. Sections may be cut from perfectly fresh material, but more satisfactory and better results are obtained from material which has previously hardened one or two hours or longer in ten-per-cent. formalin. (It is convenient to drop bits of tissue into ten-per-cent. formalin at the time of the operation or during the post-mortem examination. By the time they reach the laboratory they are usually sufficiently impregnated to be cut and stained.)

"3. Tissues already hardened in formalin should be soaked in water a minute or two to remove the formalin before cutting.

"4. Sections as they are cut may be dropped directly into the albumen solution, where they remain until needed. A solution of albumen which has been found to answer the purpose is prepared by adding to 50 c.c. by volume of egg albumen 150 c.c. of distilled water and sufficient of a solution (usually about 50 c.c.) of salicylic acid (saturated), which has been rendered slightly alkaline with lithium carbonate, completely to dissolve the albumen. The solution may be kept unchanged several weeks by adding a little gum camphor.

"5. Unhardened sections should be placed in five-per-cent. formalin three or five minutes, after which they are soaked in the albumen solution two or three minutes.

"6. Float sections on cover glasses. Remove excess of fluid with filter paper when necessary. Blot sections evenly, taking care not to use pressure enough to cause them to bear the imprint of the cloth. (The best blotting-material seems to be washed cheesecloth used in several layers. The use of filter paper, towels, muslin handkerchiefs, etc., for this purpose has not been satisfactory.)

"7. Transfer immediately to alcohol, alcohol and ether (equal parts), osmic acid, or mercuric chloride, etc., in order to coagulate the albumen and to fix the section and complete the hardening.

"8. Sections may be stained on the cover slip in various ways. For ordinary diagnostic work staining with hæmatoxylin and eosin and mounting in balsam answer well.

"9. Stain from two to five minutes in hæmatoxylin (Delafield's or Gage's).

"10. Decolorize by passing rapidly through acid alcohol—hydric chloride, 1 part; eighty-per-cent. alcohol, 99 parts.

"11. Wash thoroughly in water.

"12. Dehydrate and stain in eosin alcohol. (Eosin which has been precipitated from a saturated aqueous solution by acid stains connective tissue more sharply and gives better results than ordinary eosin. It is prepared by Fischer by adding to a saturated aqueous solution of eosin hydric chloride in excess. Filter and wash the precipitate with water until the acid is removed. Dry the precipitate and dissolve in alcohol.)

"13. Clear in oil of origanum, oil of cloves, creosote, zylol, etc.

"14. Mount in balsam after having cleaned the upper surface of the cover slip."

Dr. J. S. Thacher said that it was exceedingly important to keep fresh sections from shrinking, and this method of Dr. Hodenpyl seemed to obviate the difficulty better than any other with which he was acquainted. Sometimes by fixing the edges of the cut sections they could be prepared quite successfully.

Dr. George P. Biggs said that when a hurried examination of a tumor was required, as during an operation, he had usually been able to make a diagnosis by staining with a watery solution of methylene blue, without hardening. Of course it was a crude process, but it had served the purpose.

The President also spoke of the great utility of Cullen's method, as modified by Dr. Hodenpyl.

Dr. Hodenpyl also presented to the society a microtome and a number of specimens of various organs for examination. Those hardened in alcohol, he said, were better than those hardened in alcohol and ether.

A Report on Four Cases—Rupture of the Uterus, Leukæmia, Hemorrhagic Pancreatitis, and Gaseous Emphysema—from which the Bacillus Aerogenes was Isolated in Culture.—Dr. Charles Norris presented this report.

Case I.—The patient, a multipara, was admitted to hospital at 8 P.M. on November 16, 1896. She stated that there had been a sudden discharge of about one pint of blood from the vagina on October 26th, but no further bleeding until November 8th. Since the latter date there had been slight hemorrhage every day. She had nearly reached the full term of pregnancy. As she was in poor condition, podalic version was performed. The patient at once went into a condition of shock, but no rupture of the uterus was made out and the organ was found to be well contracted. Death occurred five hours after delivery, apparently as a result of the shock induced by rapid extraction, as the quantity of blood lost was not more than thirty or thirty-two ounces. The autopsy was made by Dr. Ewing, twenty-four hours after death. The woman was large and fat, and distinctly anæmic. There was no œdema. The right broad ligament and the tissues of the right pelvic region, around the kidney, in the mesocolon, and over a considerable area of the mesentery, were very emphysematous and infiltrated with freshly clotted blood. The peritoneal surfaces were intact. There was a large, irregular laceration involving the entire right portion of the os, and extending from one inch to one inch and a half above the internal os, completely through the uterine wall and into the tissues of the broad ligament. Below it extended one inch into the vagina. The tissues of the uterus were flabby, but otherwise normal. The lungs were congested and œdematous. The heart chambers were empty and flaccid. Minute air bubbles were found beneath the endocardium. The spleen was extremely flabby and emphysematous. The liver was soft and pale, and its surface dotted with larger and smaller air vesicles. The inferior vena cava and hepatic veins were distended with frothy fluid. The kidneys were flabby, the surface was smooth, and the capsule was free. A few medium-sized air bubbles were present. The blood which exuded from the veins at the site of the saline infusion contained no gas. There was a marked diminution in the quantity of blood in the body. The anatomical diagnosis was rupture of the uterus, acute anæmia, and pulmonary œdema.

Cover-glass preparations from the organs showed large bacilli, with capsules staining by Welch's method. They retained the stain by Gram's method, and were non-motile. Pure cultures were obtained from the liver, spleen, and uterus. A rabbit was given intravenous injections of a pure culture, and then killed after a few minutes. It was next placed in the thermostat at 37° C. for twenty-two hours. At the end of this time there was extensive emphysema of the body and of all the organs. A guinea-pig, inoculated with one cubic centimetre of bouillon in which a bit of the liver had been squeezed died in four days, with a gaseous phlegmon.

In this case, the speaker said, the portal of entry seemed undoubtedly to have been the uterus. There was a rupture of the uterus, through which the bacilli could readily have obtained a foothold in the tissues during life. They need not have been introduced during the childbirth or version, but might have found the bleeding uterine cavity a suitable soil for growth, or at least existence, before childbirth. Dead tissues, such as blood clots, were an especially favorable medium for the growth of this bacillus. The presence of gas at the autopsy was especially marked around the uterus and in the mesentery and inferior vena cava, and less marked in the liver. This fact, and the delay in making the autopsy—twenty-four hours—pointed to a post-mortem invasion, and not to an entrance into the circulation during the death agony or before. Absence of more widely distributed emphysema, as in the subcutaneous tissues, and the appearances of the liver sections, confirmed this view. Around the masses of bacilli the liver cells were not degenerated, and their nuclei stained well. Around the gas blebs there were no changes except those due to pressure.

Case II.—In this case the previous personal history was negative. For the past three months there had been pains in the joints of the upper and lower extremities, slight fever, nausea, vomiting, and constipation. When the patient was admitted to Dr. Delafield's service in the Roosevelt Hospital on December 17th, the nutrition was fair and the pulse rapid but of good force. The right knee was a little swollen and tender. The temperature was 100° F.; pulse, 100; respirations, 26. The urine was negative except for a trace of albumin. In the third left interspace, near the edge of the sternum, there was a harsh systolic murmur and a roughening of the first sound of the heart. The examination of the liver and spleen was negative. On January 4th the patient had a chill and a morning temperature of 105° F. During the week the temperature ranged between 101° and 103° F., and signs of consolidation over the left lung were present. On January 8th, after an examination of the blood, Dr. Ewing reported the case to be one of splenomyelogenous leukæmia, the leucocytes outnumbering the red blood cells. Death occurred on January 10th. At the post-mortem examination, made twenty-four hours after death, it was found that the subcutaneous tissues over trunk and extremities crepitated, and the abdominal cavity was filled with gas which when ignited burned with a blue flame. The mesenteric veins and the vena cava were distended by gas. There were no signs of peritonitis, but there was a little bloody serum in the peritoneal cavity. In both lungs there were areas of broncho-pneumonia. The spleen weighed twenty-six ounces and was emphysematous, and the follicles were much enlarged. There was evidence of a recent perisplenitis. The liver weighed four and one-half pounds, and its cut surface was of a dark slate color and very emphysematous. The kidneys were enlarged and emphysematous; the capsule was not adherent; the surface was smooth and mottled with petechiæ. The pelvic mucosa was infiltrated with blood. The pancreas appeared to be much decomposed. There were petechial spots in the mucosa of the stomach. The inguinal, cervical, and axillary glands were enlarged and deeply pigmented. The marrow of the shaft of the femur was partly fatty and reddish in color. The brain was very anæmic, and there were a few small hemorrhages in the pia mater. The ribs were very fragile, and their marrow consisted of a waxy, homogeneous substance, no red marrow being present. The lingual tonsils were a little enlarged and deeply pigmented. The anatomical diagnosis was acute leukæmia and hyperplastic splenitis.

Cultures were made from the liver and from the contents of the small intestine. Pure cultures were obtained from both places. A smear made from the contents of the intestine revealed the gas bacillus in enormous numbers. On the aerobic plates from the liver numerous colonies of the staphylococcus pyogenes aureus developed. The aerobic plates of the intestine developed the staphylococcus and the colon bacillus. The pure cultures of the gas bacillus produced gaseous phlegmons in guinea-pigs, and intravenous inoculations in rabbits killed shortly after inoculation produced marked emphysema of all the tisues and organs. Intravenous injection into rabbits of the hemorrhagic fluid contained in the gaseous phlegmons of guinea-pigs produced death, in one rabbit in four hours, and in a second rabbit inside of twenty-four hours. Examination of the sections of the spleen showed loss of nuclear staining in the cells situated around the gas blebs, and diffuse protoplasmic staining. The liver showed areas of loss of nuclear staining around many of the masses of bacilli. In

the kidney the same appearances were present around the gas blebs as in the spleen and liver. There were likewise present areas of necrosis around many of the bacterial emboli, such as were present in the liver.

These signs of a vital reaction in the tissues before death, the general distribution of the bacilli in the body, as evidenced by gas formation, the fact of the body being kept before the section in a cold room, and the marked tympanites and tenderness of the abdomen, especially marked several days before death, all pointed to an invasion of the gas bacillus during life. It was significant that several days before and up to the death of the patient the diagnosis of peritonitis was considered probable.

Case III.—The third case was that of a patient admitted to Dr. Norris' service at St. Luke's Hospital, on February 6, 1897. He was markedly alcoholic. Three days before admission he had begun to vomit large quantities of dark, clear, and clotted blood, and to pass blood in the stools. Soon after admission he grew weaker, became delirious, and died with œdema of the lungs. The autopsy was made by Dr. Norris, twenty-four hours after death. All the subcutaneous tissues were tremendously inflated with a gas which burned with a bluish flame. A foul odor was present. A number of discolored blebs filled with serum were situated on the thighs and trunk. The face was much swollen and discolored, and gas and blood bubbled out of the mouth. The scrotum was also much swollen by gas. The heart was dilated, and weighed sixteen and one-half ounces. There was much post-mortem softening in all the organs. The liver weighed six and one-fourth pounds, and its surface was rough. All the organs were emphysematous.

Anaerobic plates made from the liver and the contents of the small intestine developed colonies of the bacillus aerogenes capsulatus, which were isolated in pure culture. From the aerobic liver plates was isolated a streptococcus which clouded bouillon. From the aerobic intestinal plates the same streptococcus and the colon bacillus were isolated. The gas bacillus from this case likewise produced gaseous phlegmons in guinea-pigs, and marked emphysema of all the organs and tissues of rabbits injected just before death. Intravenous injections of the hemorrhagic fluid from gaseous phlegmons likewise produced death in rabbits. Working with the dead bacilli, no results were obtained. A filtered sugar bouillon culture, grown for two weeks anaerobically, was employed to test the effect of the toxins produced by the gas bacillus in artificial culture. Intravenous injections in rabbits (eight cubic centimetres in one, and twelve cubic centimetres in a second rabbit) produced only a slight disturbance. In guinea-pigs a marked fall of temperature and toxic disturbance were noted. In one pig six cubic centimetres, subcutaneously injected, produced in one hour a fall of temperature from 101.2 to 96.8° F. The hair of the neck and shoulders stood erect; the abdomen was tender to the touch at the site of injection, and the animal lay down on its side and stroked its mouth with its paws. There was slight trembling three hours after the injection, and the temperature was 100° F. In twenty hours the animal had recovered. A second pig received twelve cubic centimetres of the filtered toxin intraperitoneally. One hour after the injection the temperature fell from 101.8 to 95.4° F., and the animal was weak, trembling, and lying on its side. In three hours the temperature was 96.8° F., and the animal trembled violently, but it had entirely recovered at the end of twenty hours.

Case IV.—The fourth case was one of gaseous phlegmon, developing after a compound fracture of the femur. The same bacillus was isolated from this case, during the life of the patient, cultures being made at the bedside.

Dr. W. G. Le Boutillier, in discussing this report presented by Dr. Norris, said that he would like to report the case of a man who had been admitted to hospital complaining of chilliness. He had an aneurism of the left femoral artery, about the size of an egg. Six days after admission he became delirious, and the temperature reached 102° F. On June 5th the respirations were between 22 and 36, the temperature was 105° F., and he suffered pain in the region of the aneurism. The latter was found to have increased enormously in size; the skin was tense and swollen, and there was some ecchymosis around the knee. On June 7th a ligature was placed around the femoral artery, with the intention of operating upon the aneurism and removing the clot. When a portion of the clot had been turned out, there was such a rush of dark blood that the only thing that could be done was to pack the large wound and return the patient to the ward. The next day the dressing was saturated with a foul-smelling discharge. Two days later the temperature was again high. The following morning the man began bleeding, and the morning after that gas and serum were forced out of the wound. The bacillus capsulatus was found to be present, but no cocci were found.

Dr. Le Boutillier also reported briefly two other cases. A colored man, who had received an injury to the arm in the region of the elbow, developed after a few days a small lesion near the elbow, and the arm became greatly swollen. Large quantities of serum and foul-smelling gas were discharged. No cultures were made, but smear preparations showed a very large bacillus. The other case was one of gaseous abscess of the scrotum and perineum, with a small necrosed area in the centre. On incision pus was evacuated, but no bacilli were found in the cultures.

Dr. Harlow Brooks said it had been his good fortune to see autopsies on four cases—three at Bellevue and one at Charity Hospital. Dr. J. G. Adami had reported two cases in which there had seemed to be pure infection—one from the tonsil and the other from passing a sound. He thought the cases were quite common.

Dr. James Ewing said this subject had been brought before the society two years ago, and since then it had proved an interesting study to some of the members. The leukæmic case reported by Dr. Norris was one of special interest. It was unfortunate that often there was no clinical history to aid in determining whether it was a case of ante-mortem infection or not. He believed that rapid putrefaction in such a case would indicate an ante-mortem infection, and that in cases of infection occurring after death the progress was slower and the bacilli were found more in the area of infection, and were not spread through the body as in the other class of cases. He was very desirous of learning what relation the bacillus capsulatus bore to the streptococci and other cocci. It was at least suggestive that infection with the bacillus capsulatus was often associated with ruptures of the uterus, of blood-vessels, or with the occurrence of profuse hemorrhage.

A Primary Carcinoma of the Kidney.—Dr. Harlow Brooks reported this case. He said:

"The patient was a maiden, forty-eight years old She was born in Ireland, but the greater part of her life had been spent in America, in the occupation of maid. She was always anæmic in appearance, and a peculiar tremor of the head has been present for several years, for at least over ten years back. Her general health, however, appears to have been good. In March, 1897, she is said to have had pneumonia, and she stated that at this time she had undergone an operation for pus in the lung. In September, 1897, she entered Trinity Hospital, to be treated for an injury of the thigh, and was shortly after seen by the attending sur-

geon, Dr. Nelson H. Henry, who made the usual surgical examinations of the injured extremity. Nothing peculiar in regard to her case was noted either before by the nurse, or at the time of the examination, though a general physical examination was not made at this time, as the patient made no complaint other than of the injury. A few moments after leaving the ward Dr. Henry was recalled and found the patient pulseless and cyanosed. Froth was exuding from the mouth. Artificial respiration and the usual stimulants were applied, with no apparent effect, and in a few minutes the patient was found to be dead.

"The autopsy was performed on the same day, while the body was still warm. I shall omit in this report all the details of the autopsy, touching only on those points which seem most noteworthy. Suffice it to say that extensive embolism of the left pulmonary artery was found, and its origin sufficiently accounted for by an endocarditis of considerable extent and apparently of quite recent origin; possibly this was a resultant of the previously existing pneumonia, abundant traces of which still persisted, together with a thickened pleura.

"The brain was poorly formed, showing considerable asymmetry in its contour. The convolutions were flattened, small, and irregular. A few convolutions showed a gelatinous degeneration of their substance. These changes no doubt account for the long-standing tremor and for the simple and child-like appearance of the face, as well as for the lack of feminine type in the form of the body. These lesions, coupled with their manifestations, are very interesting in themselves, but of course have no connection with primary carcinoma of the kidney, for which the case is reported. It seems proper, however, to state that no evidence of syphilis was found other than the possible relations to this disease found in the brain, though the autopsy was very thoroughly and carefully made.

"The right kidney was found of about the usual size and was normally located. The capsule was neither adherent nor thickened. The cortex was thick and regular, and all the markings were found to be distinct. The tissue was firm. The vessel walls showed no abnormalities, but the capillaries everywhere were greatly congested and the cut surface dripped blood and serum. The cortical portions of the kidney were somewhat cloudy, and a general cortical parenchymatous degeneration seemed to be present.

"The left kidney presented the most interesting feature of the case, and the one which I think justifies me in presenting the case to you. On the outer surface of the left kidney was found a globular mass, smooth, subcapsular, and of less tension on palpation than the remaining portions of the kidney tissue. The vessels of the capsule covering this mass were greatly congested, and this mass, indeed the entire kidney, was found surrounded by considerable inflammatory tissue, most of which was noted as being of probably rather recent formation. There was found one vessel of about 1.5 mm. calibre, which entered the tumor mass directly through the capsule. The kidney being opened, the tumor mass was seen to be sharply differentiated off from the kidney structure by a thin but well-defined and complete capsule of connective tissue. The tumor was spherical in form, and measured sixty-three millimetres in diameter. It had a centre of a white cartilaginous appearance, and from this radiated about in regular spoke-like lines a stroma of similar substance. Between these radiating and anastomosing whitish paths were found islands of brownish tissue, resembling that of the remaining and uninvolved portions of the kidney. The tumor may be said strongly to resemble a series of the pyramids of the kidney arranged about a common centre. Vessels were not numerous in the stroma of the tumor, though the capsule was found to be quite vascular. The tumor was so located in the substance of the kidney that its central point was situated at about midway in the kidney and about the middle line of the zone bordering on the pyramids, but its most internal diameter jutted into the pelvis of the kidney, while its external periphery, as is well shown in the specimen, projected outward from the normal kidney contour. A diagnosis of adenoma was made from the gross appearances of the mass, and, as already stated, no other nodules of neoplastic nature were found in any other part of the body. Neither was any glandular enlargement present. Microscopic examination of the section taken from various parts of the tumor give in all instances the same picture, that of carcinoma of the adenomatous type.

"I am induced to believe that the growth was originally an adenoma: First, from its shape and location, which are those indicative usually of kidney adenoma. Second, from the fact that, while the growth was evidently of some months' standing, as is indicated by the thick capsule of fibrous tissue about the tumor, yet no metastases were found. This would seem improbable in a growth originally malignant in character, the probable age of which is considerable, and at the same time growing in an organ with so extensive a lymph supply as is present in the kidney. Third, in certain parts of the sections of the tumor the structure is typically that of adenoma; this is especially true in those portions in which a connective-tissue stroma is abundant, as is the case near and in the limiting capsule of the tumor.

"Adenomata of the kidney are quite common, and as adenomata in other locations are quite prone to carcinomatous change, it does not seem in the least strange that it should take place here. We have, at Carnegie laboratory, a specimen of adenoma of the kidney, which shows in area quite typical carcinoma. Delafield, in speaking of adenoma of the kidney, says that when these adenomata take a malignant course they are spoken of as carcinomata.

"Carcinoma is among the more rare of the primary tumors of the kidney, numerous cases of it, however, are reported. Up to 1886 I have found one hundred and twenty-seven cases of primary cancer of the kidney reported, but among these are some congenital tumors and others in which the description is that more characteristic of the more common growth, sarcoma. It is more than probable that a considerable number of these growths were called cancer simply because they appeared to be of a malignant nature, and in many of these no microscopic examination was made. Dr. Shrady reported a case of primary carcinoma of the kidney before this society in, I think, 1881. Harrison states, in the 'Twentieth Century Practice,' vol. i., that carcinoma, when primary in the kidney, is usually confined to a single kidney, as is the case in the specimen I present.

"It seems unnecessary to speak of the impossibility of ante-mortem diagnosis in such a case as this, and the chief interest seems to centre in the rarity of the growth and in its probable origin from a pre-existing adenoma."

Hemorrhagic Pancreatitis with Fat Necrosis; Abscess of Liver; Infection by Bacillus Aerogenes Capsulatus.—Dr. John H. Larkin presented this case. He said:

"The family history of the patient was negative, and there was nothing of note about his personal history, except that he had gonorrhœa in the fall of 1896. His last illness began, one month before he came under observation, with shooting pains in the right foot, leg, and knee. These pains have recurred in severe attacks ever since, and have kept him from his work. On April 19th, after drinking ice water, he experienced terrible cramps in the right hypochondriac region, lasting all night. During this time he had chills and

fever, and the next morning he noticed that he was markedly jaundiced. The vomitus was dark colored, 'like mud.' The bowels have been regular until three days ago; since then they have been constipated. On admission his temperature was 104° F.; pulse, 78; respiration, 36. He was well nourished; the skin and conjunctivæ were yellow; the heart and lungs were normal. The liver extended from the fourth space to the costal border. The splenic dulness began in the seventh space mid-axillary line, and extended to the costal border. The abdomen was distended and tympanitic, and there was marked tenderness in the epigastrium. There was no œdema of the extremities. Over both forearms and hands, and over the lower part of the abdomen, there was an orange-colored, macular eruption, varying in size from that of the head of a pin to a ten-cent piece, irregular in outline and coalescent in places. The patient was delirious. The blood examination showed the red cells to be normal in shape and number, and 22,000 white cells per cubic millimetre.

"Autopsy: The autopsy was made six hours after death, by Dr. Ely, to whom I am indebted for the privilege of reporting this case. The body was well nourished, and the skin slightly jaundiced. When the peritoneal cavity was opened, a quantity of blood-stained fluid welled out, estimated to be about eight ounces. In the left hypochondriac region, behind and below the spleen, were some blood clots and fibrous adhesions. The whole heart was somewhat enlarged; there was an abundance of subpericardial fat; the muscle was somewhat hypertrophied; the valves and orifices were normal; and there was very slight atheroma of the aorta around the coronary openings. The lungs and stomach were normal. On passing the finger down the duodenum, a hard mass was felt in the region of the head of the pancreas. The gall bladder was moderately distended with thin, yellow bile, and contained about a dozen small gall stones. In the papilla, at the opening of the common bile duct, were lodged three small gall stones. The liver was slightly enlarged, and in its tissue were a number of small circumscribed necrotic areas, containing what looked like pus. There was one larger, ragged area of necrosis, containing red granular clots and detritus. The tissue surrounding this, and reaching nearly to the surface of the liver, appeared to be necrotic and somewhat soft, and was riddled with open canals, from which exuded frothy, blood-like fluid. The spleen showed parenchymatous hyperplasia and marked congestion. The head of the pancreas, on section, was firm, but contained areas of necrosis, hemorrhagic in appearance. The body of the organ was very largely disorganized, being bloody and soft, and below this, and lying behind and below the spleen was a large amount of soft, red, granular clot. Both the suprarenal capsules were necrotic. The kidneys showed parenchymatous degeneration.

"The following gives in detail the results of the microscopical examination of this case:

"Changes in the liver: There are chronic venous congestion of the liver, dilatation of the central vein and surrounding capillaries, with consequent atrophy of liver cells in the immediate vicinity. In the examination of many sections taken from different parts of the liver, one gets different pictures of the lesions present. There are many areas of focal necrosis scattered in the liver parenchyma. These areas are in some respects identical with many of focal necrosis seen in typhoid, diphtheria, and tuberculosis. They are immediately around the central vein, which is dilated. They are made up of liver cells alone, but as yet, for the most part, preserve their outline, are entirely devoid of nuclei, and stain faintly with eosin. The capillaries in the periphery of these necrotic areas are intensely engorged with red and white cells. The central veins in many places are empty; in other places they are filled with bacterial thrombi. Not all the central veins are surrounded by necrotic areas. In other portions of the lobules we have the same identical focal necrosis of liver cells, with and without the central mass of bacteria. In other sections examined there is no focal necrosis, but intense venous congestion; whole lobules changed into large blood lakes, with widespread disintegration of liver parenchyma. In still other sections, all one can see is a complete destruction of liver parenchyma from centre to periphery. There is loss of capillaries—a granular and fragmented nuclear mass, a condition not unlike the picture of acute yellow atrophy of liver. Again, in some sections there is a loss of liver parenchyma, these empty spaces or air-holes, irregular in outline, larger and smaller, with flattened, necrotic, and non-nucleated cells, making up their border. The constant presence of bacteria at their periphery, and of swarming masses of bacterial emboli in the capillaries and central veins, is not to be lost sight of. In other sections the principal lesion is abscess formation, both of the miliary and large variety. There are loss of liver cells and replacement by a broken-down granular debris, leucocytes, fragmented nuclei, with flattening of necrotic liver cells at the periphery. In the larger abscess cavities the central detritus had fallen out, leaving only a narrow band of leucocytes and granular detritus with necrosis of liver cells at the periphery.

"Changes in the spleen: The changes in the splenic tissue are, in a great many respects, identical with those in the liver, with the exception of abscess-cavity formation. The necrotic foci are, however, smaller and more numerous. There is little nuclear fragmentation. Other sections show intense venous congestion with atrophy of splenic pulp. The occurrence of gas blebs, œdema of trabecula, and a homogeneous, glassy condition of blood-vessels was at times noticed.

"Changes in the kidneys: There is no chronic productive inflammation. There is parenchymatous degeneration of the epithelium of the tubules. The capillary tufts in many places are plugged with bacterial emboli, which caused the subsequent death of the surrounding parenchyma.

"Changes in the heart muscle: There are interstitial myocarditis and some slight fatty infiltration. The heart-muscle fibres seem to be broken up into short rods, separated from one another perhaps by a dissolving of the cement substance. Scattered here and there are the same bacterial emboli, with the muscle fibres around broken down and necrotic, and entirely devoid of nuclei. Gas blebs in the myocardium are present in some sections, absent in others. We have the same focal necrotic areas, not attended by bacteria which could be stained in tissue, the necrosis consisting simply of a swelling and granular condition of muscle cells without nuclei, and the whole standing out sharply against the surrounding normal heart tissue.

"Changes in the pancreas and fat tissues: There is diffuse hemorrhagic infiltration of the interlobular and intercellular fat tissue, with atrophy and compression of the fibrous tissue. In the interlobular tissue in other sections, leucocytes and fibrin outnumber the red blood cells, while the fat cells, filled with red blood, make large irregular blood lakes in which can be distinguished the faint outline of the fat cell. The areas of necrosis in the peripancreatic fat are in places oblong; in other districts of irregular, spade-like form the whole mass is made up of a granular detritus devoid of cells or nuclei. The outline of the fat cells is lost or indistinct, the island with irregular borders shading off into the surrounding fat tissue. These

necrotic areas stain faintly with eosin; some have a limiting zone of leucocytes and small round cells, with many yellowish-colored and irregular shaped crystals in the periphery. In other sections the replacement of the fat tissue by polynuclear leucocytes, small, round, spindle, and large mononuclear cells, is the predominating feature, together with numbers of smaller and larger rounded, needle-shaped crystals—some staining faintly or not at all with eosin, others having affinity for the nuclear dyes. These spherical bodies are in the fat cells at the periphery of the necrosed area, and are perhaps nothing but fatty-acid crystals. In the interlobular tissue, in other sections, instead of the above lesions being presented, there is simply necrosis of the connective tissue, the interlobular necrosis leading to the large areas of fat necrosis in other parts. In still other sections the fat tissue is normal, but shows productive inflammation of the interlobular fibrous septa, while the peripheral portions of fat show large, irregular, diffuse patches of small, round, and spindle cells with delicate-walled blood-vessels, and not a few giant cells. These areas look as if there was evident replacement of some of the necrosed portions by what appears to be a fibrocellular tissue. The foregoing changes are those which have taken place in the peripancreatic fat tissue, and are perhaps secondary to those changes to be described in the pancreas; but that the lesion could be primary in the peripancreatic fat tissue and secondarily invade the pancreas is, I think, an undeniable fact. The lesion, after all, amounts to nothing more than an extension by continuity.

"Pancreas: Some portions of pancreas are perfectly normal; in other places the fibrous tissue between the lobules and acini is considerably increased in amount; in still others the fat tissue predominates. In many sections there is extensive fatty infiltration, both in and between the lobules. There are numerous islets of focal necrosis in the parenchyma, with scattered cells not arranged in definite acini. The interlobular connective tissue shows œdema and diffuse hemorrhagic infiltration, the infiltration going in between the lobules to a considerable degree. The interlobular spaces in other places are simply filled with clumps of dark-brown material, containing many hæmatoidin crystals. The parenchyma cells in these areas are necrotic and devoid of nuclei; in other lobules, especially in the districts of the intralobular fat necrosis, the regularity of the acini is lost, the whole lobule being made up of a confluent mass of degenerated cells and clumps of protoplasm devoid of nuclei.

"That the process in the pancreas shows both old and recent hemorrhage, I think, is certain. Many of the lobules show entire replacement by dark-brown fragmented masses, with occasional hæmatoidin crystals, while the more recent hemorrhages are simply diffuse hemorrhagic areas of red blood cells and leucocytes. Fat tissue taken from the regions of the kidneys and suprarenal glands shows a lesion identical with that of the peripancreatic fat. On account of the abscess formation in the liver, with subsequent infection by the bacillus aerogenes capsulatus, portions of the viscera, including the heart, lungs, liver, spleen, kidneys, and pancreas, together with specimens of fat tissue, were hardened in absolute alcohol. These sections were utilized for staining bacteria in tissue.

"In all the tissues examined a bacillus was found which stained quite readily with Gram's, Weigert's, and Loeffler's method. The bacilli were in clumps and clusters in the capillaries and blood-vessels, and the centres of necrotic foci. It occurred in short chains having square-cut edges, the individual ones showing rounded ends and staining diffusely throughout with aniline dye. While for the most part the necrotic foci in the liver, heart, and kidneys contained a central mass of bacteria, yet there were many other focal areas of necrosis, especially in the spleen, liver, and heart, in which no bacilli could be demonstrated by the above stains.

"The bacteriological examination was made by Dr. Charles Norris. He was able to isolate two species of bacteria—one, the bacillus aerogenes capsulatus, which he obtained in pure culture; the other, a bacillus whose morphology is similar to that of the bacillus coli communis. It is non-motile, and decolorizes by Gram's stain; on lactose-litmus-agar acid is produced; no indol is formed after three days; invisible growth on potato. No gas is produced in grape-sugar-agar, and there is no coagulation of milk after four days. Although the exact nature of this bacillus is not known, a further study of it will undoubtedly be most interesting."

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CANCER DEBATE—IMMUNIZATION OF ANIMALS AGAINST STREPTOCOCCAL INFECTION—OBSTETRICAL SOCIETY—MESSRS. CARTER AND HORSLEY—MERCER'S HOSPITAL—MR. ENSOR—THE LATE MR. LUND.

London, February 11, 1898.

The discussion on immunity and latency after operations for mammary cancer was resumed on Tuesday by Sir T. Smith, who deprecated dogmatic conclusions being drawn and said that little more was known of the nature of the disease than when it was discussed by the Pathological Society in 1874. The newer operation he feared had been adopted somewhat hastily in this country, and its advocates spoke with a kind of pity of those who practised the older method. They held that cancer was a local disease and that a patient was "cured" if there was no recurrence in three years. It needed a very strong belief in its purely local nature to justify some of the more formidable procedures that had been practised. He could not allow that cases were merely local when the glands beneath the clavicle were involved and all the growth could not be got away without removing the arm. He thought the growth had ceased to be a local disease long before it was tangible, and he regretted the use of the term "cured" as it misled the public and in the present state of our knowledge was premature. He had removed glands from the axilla twenty-four years after the removal of the breast, no recurrence having occurred in that period, and in a case quoted by Mr. Cheyne hard glands left in the axilla did not need removal for fifteen years. He always removed all visible diseased tissue and generally the whole breast, and mentioned some cases in which there was no recurrence for more than seven years after removal of the nipple and areola.

Mr. Hutchinson was a believer in cures in the sense that recurrence did not take place, and he had known patients quite well twenty years after operation. At one time he used to clear out the axilla, but now he did not meddle with it unless he could feel something. The old operation gave a fair chance of cure if done early, and even if some general infection had occurred the removal of this large focus of infection was beneficial. He attributed the improved results of the present time to earlier operations rather than to their greater extent.

Mr. Nunn also held that the surgeon should operate early rather than widely. In some cases cancer seemed to be an affection of the lymphatic system, when no

operation could be "adequate." He thought eight per cent. of patients lived from ten to twenty years after operation.

Mr. Howard Marsh always removed the entire breast and opened the axilla, as it was often impossible to detect enlarged glands through the skin. He did not remove the pectoral muscle, as he knew of no case of recurrence in muscular tissue. But the skin and the fascia with its lymphatics were seats of recurrence and should be removed.

Mr. Barker said for the last twelve years he had always cleared out the axilla, taking away all fat and glands up to the clavicle and stripping off the fascia from the pectoral muscle. This plan he did not consider increased the risks, while it lessened intercurrent troubles and added to the comfort of the patients. He had had only one death from this operation. He thought removal of the glands was the chief factor in improved prospects. He agreed with Mr. Hutchinson that the least promising cases often turned out the best. In one case he removed a mass of cancerous glands from the axilla and a large tumor from the breast, and the patient was quite well nine and one-half years afterward.

The discussion was then again adjourned.

The immunization of animals against streptococcal infection was brought forward in the Pathological Society is a paper by Dr. Bokenham. His culture medium is fresh veal broth with peptone and salt solution boiled for several hours under pressure and kept for three weeks or more. The virulence of the organisms he finds to be increased by passing through rabbits. The filtrate is highly poisonous to these animals, producing glomerulo-nephritis and hemorrhages into the alimentary canal. In horses and asses it causes a reaction and rise of temperature followed by tolerance to subsequent injection. Repeated inoculations are necessary to obtain an immunizing serum. If taken too soon, before all reaction has subsided, the serum is apt to cause local reaction when injected into another animal; but taken later there is no disturbance. It may be doubted whether there is a true antitoxic action, but marked increase of phagocytosis can be demonstrated. Dr. Bokenham has had many opportunities of seeing the effect of the remedy in streptococcal infection in man. He always observed speedy loss of the headache and restlessness, the patient getting drowsy and the skin moist. The temperature might rise at first, but it soon came down and could be kept down by repeated injections. In erysipelas the erythema may disappear in twenty-four hours. He begins with ten cubic centimetres and this dose may be repeated several times. In animals immunity seems to last six weeks or more. In two cases of ulcerative endocarditis one patient recovered after one hundred and fifty cubic centimetres had been injected altogether; in the other there was only temporary relief. It was remarked by the president that the specimens of nephritis resembled those seen in scarlet-fever cases. Dr. Bokenham's paper was well illustrated by charts and lantern slides.

The annual meeting of the Obstetrical Society was held on the 2d inst. The retiring president in his address said the alteration in the certificates given to midwives in deference to the Medical Council has in no degree diminished the number of candidates, which continues to increase. He also said that the work of examining midwives was taken up as a temporary duty (!) when the society could not induce the government to move in the matter. It would be a strange thing if every one dissatisfied with a government were to take his own course. The society has no authority whatever and its certificate confers no privilege. It is a pity the Medical Council "climbed down" from the sensible position it once took toward the society.

The fight between Mr. Brudenell Carter and Prof. V. Horsley has, as I anticipated, been transferred to the press. The logomachy is amusing to those of us who know both parties, but will be of less interest perhaps to you, so I must deal with it briefly. Mr. Carter came out with a series of paragraphs contradicting Mr. Horsley's statements about the Medical Council. Each of these paragraphs began with "It is not true." Mr. Horsley replies to each of these assertions, "It is true," and adds the "proof," which for the most part consists of extracts from the published minutes of the council. He preserves a dignified attitude as to the shower of personalities to which Mr. Carter treated him. It is a disagreeable point in Mr. Carter's controversies that he is so fond of reminding opponents of his age and his knowledge of English. To talk of having studied medical politics before Mr. Horsley was born is surely a sign of weakness. To suggest that the grammar of his opponent's sentences might be improved only shows his own self-consciousness. No one doubts that Mr. Carter can write English; but he is not the only medical man who can do so, and the possession of that accomplishment is no guarantee that his views are correct. But this is not the first time that Mr. Carter has imputed youth and faulty English to opponents and smiled over his own age and grammar, as if they settled all controversy.

The managers of Mercer's Hospital have obtained a surgeon. The old story—some one is always ready to take a vacancy, whatever the honor or dishonor attaching to the appointment. So it is at Newport—a candidate has already been found for the vacancy created by Mr. Ensor giving up the ophthalmic surgeoncy for the honor of the profession. All honor to men like Mr. Ensor. Their supplanters should be sent to Coventry.

Mr. Edward Lund died last Friday, aged seventy-five years. He settled at Manchester fifty years ago, and has been for most of the time associated with the medical school there. He took an active part in the union of the school with Owens' College, and became professor of surgery to that institution. As surgeon to the infirmary he had a great experience and he possessed a remarakble power of teaching. Those of your readers who have read his contributions will have been charmed with his lucid style and apt illustrations. He adopted the antiseptic system from its commencement. He has been examiner, Hunterian professor, and member of the council of the Royal College of Surgeons.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE INFLUENCING OF SEX IN THE EMBRYO—THE NEW TUBERCULIN—TRAUMATISM AND PARALYSIS—SOME RARER AFFECTIONS OF CHILDREN—THE GONOCOCCI QUESTION.

BERLIN, January [illegible], 1898.

This new year, like 1896, began with a sensational announcement. Then it was the Roentgen rays; now we have the publication of Professor Schenk, of Vienna, regarding the influence upon the sex of unborn children, to excite the medical profession and the laity. In practice, he says, he has had repeated opportunity of testing his theory, and has often given advice as to what measures should be adopted to gain the desired result, and has met with success. But more than this he has refused to say, and not even the most skilful interviewers have been able to "draw him out." We must therefore patiently wait till the fall, when he has promised to publish an extensive treatise upon the subject, and to place it before the Imperial Academy of Sciences.

In the Gesellschaft der Charitéärzte, results of

tuberculin TR were reported and discussed. Dr. Huber had four non-tuberculous and fifteen tuberculous cases, and of these four fell fully within Koch's severe indications. Huber concluded from his results that tuberculin TR was generally neither harmful nor beneficial; the good results sometimes attained might well be attributed to the improved hygiene and diet. Burghart arrived at the same conclusions. His experiences were with five pyretic and five apyretic phthisical cases. As a rule, there was a gain in weight. He regarded the reaction as more severe than that from the old tuberculin, and yet not so characteristic, for persons in good health as well as sufferers from other affections may react with fever. Huber at the same time experimented with guinea-pigs, with the following results. The injections were made in part before, in part after the inoculation with tuberculosis. Those animals who received tuberculin TR usually died earlier than those not receiving it. Thus the conclusion arrived at after trials upon man and animals was thoroughly unfavorable to the new tuberculin.

Dr. Kaplan reported his investigations upon the relation between progressive paralysis and traumatism to the Psychiatrische Verein zu Berlin. Among five hundred and forty-six patients he found a history of trauma but twenty-four times, equal to a percentage of only 4.4. In but 1.5 per cent. was there a seeming connection between the traumatism and the disease. In twelve cases in which the first symptoms appeared after a traumatism, a history of syphilis was obtained. Kaplan therefore believes that traumatism is never a cause of paralytic dementia. Usually syphilis is the cause. It matters little that frequently a history of syphilis cannot be obtained, for often in unmistakable cases of syphilitic manifestations, as, for example, gummatous processes, no positive history is to be obtained. He holds, and his views were supported by several other authorities, among them the celebrated Möli, that the psychical depression following trauma is to be looked upon as simple and not progressive dementia. These views are naturally of the greatest importance from a medico-legal point of view.

At the first meeting this year of the Berliner medicinische Gesellschaft, Beckmann showed a child with a healed abscess of the brain. Previously but ten cases have been reported. The patient was six years of age. At first the mastoid process was trephined, but as the symptoms, viz., fever, dizziness, headache, rigidity of the nucha, and vomiting, reappeared within two days, a portion of the posterior region of the skull was chiselled away, the dura slit open, and four or five cubic centimetres of thick, yellow, odorless pus discharged. Thereupon the case went on to recovery. It is remarkable that, in spite of the abscess developing within a few weeks, no damage to the brain substance itself resulted. There were no motor disturbances. Recovery at such an early age has been observed in but one other case heretofore. As another rare affection of childhood Professor Heubner demonstrated a case of bronchiectasis in a patient three years of age. Remarkable and interesting about the case was that after measles there developed a tuberculosis about and upon the bronchiectatic areas. The secondary infection with tubercle bacilli could be very clearly demonstrated. Professor Virchow declared the case to be one of greatest rarity; there were changes in the parenchyma of the lung such as are met with in the extremest cases only of bronchiectasis. In connection with this case Hausemann reported a similar one of bronchiectasis with secondary tuberculous infection. Although the pus in the bronchiectatic cavity gave almost pure cultures of tubercle bacilli, no trace of either caseous degeneration or tuberculous infiltration could be found in the neighboring parts. At the same meeting Virchow demonstrated a series of cholesterin cysts of the spleen and upper portion of the abdomen.

There was also a protracted debate upon the treatment of gonorrhœa in prostitutes. The chief speaker, Dr. Behrend, who has been medical director of the local institute for the treatment of diseased prostitutes, and who therefore possesses an extensive experience in his department, stated that but little weight is to be attached to the presence of gonococci or to their absence. Often they are present in large numbers in a case in which at other times they are absent, and men as well as women may be infectious even if the most careful examination fails to reveal the presence of any gonococci. Behrend therefore advises that the treatment be guided by the clinical manifestations. The microscopical demonstration is of positive value only in cases in which it is really superfluous; in other cases it is so unreliable that one may dispense with it entirely. As for the treatment of prostitutes, Behrend has had the speediest results with vaginal douches of alum, cauterizing the cervix with ten-per-cent. solutions of chloride of zinc, and when the vaginal epithelium was destroyed through eczematous processes dusting these places with iodoform powder. He scarcely ever treats the urethritis, vulvitis, and Bartholinitis, for these heal spontaneously. In fact he warns against any local treatment of the urethra, for there is danger of thereby causing extension of the inflammation to the bladder and kidneys. Furthermore, he declares that beyond a doubt many cases of chronic gonorrhœa in women are never entirely recovered from, even though there may be periods in which they cease to be infectious.

SCHLEICH'S SOLUTION FOR GENERAL ANÆSTHESIA.

To the Editor of the Medical Record.

Sir: In experimenting with Schleich's solutions for general anæsthesia, my friend, H. P. Weidig, Ph.D., according to a letter received from him under date of January 12, 1898, has found that only a part of the sulphuric ether—one of the components of Schleich's solutions—is in real combination. Analysis has shown that:

No. 1 contains 53.76 per cent. in volume of free ether; No. 2, 46.64 per cent.; No. 3, 36.96 per cent.

Or, the same expressed by weight percentage: No. 1 contains 44.06 per cent.; No. 2, 37.12 per cent.; No. 3, 28.41 per cent.

This condition explains the possibility of the appearance of asphyxia during narcosis, as it has been meanwhile observed by a number of colleagues, and particularly in those cases, I believe, in which the new anæsthetic solution was not administered by the rapid drop method. It also enables us to understand how it could happen that now and then some or marked cyanosis and even broncho-pneumonia (one case) set in.

Dr. Weidig and myself have since experimented with an anæsthetic solution which contains chloroform and ether "in molecular combination," and shows no free ether whatsoever. We have called it "Schleich's improved solution for general anæsthesia" ("M. S." = molecular solution). With the help of a petrolic ether of a lower boiling-point, the improved solution can also be adapted to the temperature of the body (100.4° F.), to 104° F. (Schleich's solution No. 2), as well as to 107.4° F. (Schleich's solution No. 3).

A more detailed account of these interesting facts will be found in my article, read before the last meeting of the New York County Medical Society, December 27, 1897, and which, according to mutual arrangement, will soon appear in the columns of your esteemed journal.

I believe that these improved solutions will be void of the little annoyances that have still proven a drawback in the administration of Schleich's original solutions. Experience must demonstrate whether this expectation will be verified by clinical facts.

WILLY MEYER, M.D.

NEW YORK, February 16, 1898.

EARLY VIEWS OF APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It is not to lessen the estimation in which Dr. McBurney is held by the medical profession, but for the sake of historical truth, that the following is published:

Traube, in his classical work ("Gesammelte Beiträge zur Pathologie und Physiologie," Berlin, 1871, 2d book, 1st section, p. 55), publishes a case under the headline, "Inflammation of the Connective Tissue and the Peritoneum around the Cæcum Accompanied with Fæcal Obstruction," and gives the following history:

"W. L——, hired man, thirty-two years old, received into the Charité Hospital, March 22, 1850. The disease commenced with a pain, which manifested itself in the lower part of the abdomen, about in the middle, between the right anterior iliac spine and the navel, first in a moderate degree, but after a few hours it grew in vehemence, and up to yesterday noon continually increased in intensity.

"March 24, 1850, abdomen very much distended, tense, and sensitive all over to pressure, on the right side more so, and in the highest degree at the point mentioned between the iliac spine and the navel [*ibid.*, page 56].

"March 25, 1850, abdomen equally distended, but soft and only sensitive to pressure in a small place above Poupart's ligament. Besides, there is to be felt in the designated place a deep-lying small cord, two inches long, which seems to run parallel to the extreme outside part of Poupart's ligament."

This is sufficient evidence, but some may object, claiming that he did not realize the importance of the inflamed and perforated appendage in these kinds of troubles. We will therefore cite a case which he observed in the year 1857 (*ibid.*, page 358).

"Perforation of the Processus Vermiformis with Fæcal Vomiting." The history of the case is of the usual type, but the post-mortem is very interesting, showing conclusively that modern writers have not improved on his "Pathologie." It reads as follows:

"In detaching the blind end of the intestinal coil—cæcum—a small quantity of pus showed itself. By looking closer, it was evident that the pus was escaping out of a cavity the size of an apple, which cavity was formed by the peritoneum itself, and which was situated in the right part of the small pelvis and completely filled with pus. Into this cavity protruded the vermiform process, extraordinarily distended and very rigid.

"The appendix, close above the yellowish-colored opening, was perforated, and it contained in the distal end beyond the place of perforation two egg-shaped stratified fæcal stones of a pale yellowish color, easily cut, and, on cross-section, of a brown and striated appearance. On the peritoneal lining of the intestinal coils which formed the walls of the abscess there had been already previously seen a few yellowish-colored, small, and crumbled particles, evidently the remainders of a fæcal stone which got through the mentioned opening."

And, finally, to show how intimately Traube knew the clinical and pathological finest details of appendicitis, I shall quote a review by him of thirty cases of peritonitis consecutive to perforation of the appendix (*ibid.*, page 360).

"Among the thirty cases of peritonitis following perforation of the process vermif. [leaving out the unessential], in close consideration of our cases, there manifests itself yet a second, for the diagnosis very remarkable deviation from the usual type of the disease, namely, that neither the pains nor the morbid sensibility to pressure present themselves in the right iliac region the most. It is rather difficult to account for the cause of this phenomenon. If we wanted to derive it from the supposition that the focus of inflammation is at a great distance from the abdominal wall, and therefore not very amenable to palpation in the right iliac region, then pain on pressure could so much less be produced in the left iliac region.

"But whatever the cause may be, it seems to be a fact that a peritonitis depending upon a perforation of the process vermif. can be present, and yet the pain and the morbid sensitiveness to pressure may not have the main seat in the region iliac dextra."

I do not like to be critical, but it would be hard to suppress the opinion that quite a few of our modern writers could afford to imitate this fair example of how sincerely Traube admits that he does not know. How many theories have been brought forward, since Traube, to explain these peculiar phenomena? And none of the writers of to-day had even an inkling that this phenomenon was known to Traube. In the same way, I presume, Dr. McBurney has detected a thing which was found by Traube fifty years ago.

ADOLPH ROSENTHAL, M.D.

100 STATE STREET, CHICAGO,
February 12, 1898.

"A MODIFIED INCISION AT THE OUTER BORDER OF THE RECTUS MUSCLE FOR APPENDICITIS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your last issue a criticism of the anatomical data contained in my article of December 11, 1897, appeared. I shall be as brief as possible in my reply. I had devoted some time to the study of the innervation of the rectus, before I wrote my paper, but I must frankly confess that I was unable to arrive at definite conclusions so rapidly as your correspondent has done. No doubt, the lower intercostal nerves mainly supply the rectus, and this I distinctly state. The question at issue is whether or not the ilio-hypogastric supplies the lower portion of the muscle. In support of this view I might mention that the ilio-hypogastric is a direct continuation of the first lumbar. It follows a course very similar to that of the twelfth dorsal, and its hypogastric branch is not infrequently joined with that nerve (Quain). It perforates the sheath of the rectus, according to the late Henle, of Gottingen, no mean authority. In making the modified incision for appendicitis we always expose a nerve which has perforated the sheath of the rectus and which I have taken for the ilio-hypogastric and not for the twelfth dorsal. That this nerve supplies the rectus I have sufficiently demonstrated to myself and my assistants in about fifteen dissections *in vivo*. Any handling of the same will immediately cause circumscribed contractions of the rectus. I might, furthermore, quote William H. Flower, who in his "Diagrams of the Nerves," London, 1881, figures the ilio-hypogastric as supplying the rectus (Plate IV.). As regards the lineæ transversæ of the muscle, I am acquainted with their number and position, and do not think they are "scattered at random" throughout the muscle. I have assumed that there is generally present a fourth linea transversa between the umbilicus and the symphysis, and in speaking of atrophy of part of the rectus I had

in mind that portion lying between the third and fourth intersections, which I think can be easily inferred from the text of my publication. The question of the exact situation of the temporary muscular atrophy is really, I think, one of very little importance. I think ilio-hypogastric and ileo-hypogastric are both correct. The late Professor Hyrtl, of Vienna, who was not only an eminent anatomist but also a great classical scholar, uses ileo-hypogastric. English writers use the term ilio-hypogastric, but that, I fancy, does not make the spelling of ileo-hypogastric incorrect.

F. KAMMERER, M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending February 26, 1898:

	Cases.	Deaths.
Tuberculosis	201	102
Typhoid fever	8	1
Scarlet fever	157	20
Measles	427	10
Diphtheria	159	26
Laryngeal diphtheria (croup)	10	5
Chicken-pox	20	0
Cerebro-spinal meningitis	1	11
Pertussis	3	0
Parotiditis	2	0

The Number of British Doctors.—The issue for 1898 of the invaluable Medical Directory shows, it is true, that there has been an increase in the number of registered practitioners over the number for last year, but the increase of 1898 over 1897—namely, 619—is less than the increase of 1897 over 1896, which was 958. The whole number of practitioners spread throughout the empire for 1898 is 34,903, as against 34,284 in 1897, and they are distributed as follows, the numbers given in brackets being those of 1897. for comparison: Number of practitioners in the London list, 6,081 [5,992]; in England, excluding London, 15,400 [15,081]; in Wales, 1,081 [1,062]; in Scotland, 3,412 [3,369]; in Ireland, 2,615 [2,598]; practitioners resident abroad, 3,770 [3,652]; naval, military, and Indian medical services, excluding those which appear also in other lists, 2,521 [2,510]; too late list, 23 [20]. During last year 599 members of the profession died, as against 497 in 1898.—*Lancet.*

The General Medical Council of Great Britain and the Medical Profession.—There are dissensions in the camp of the British General Medical Council. Mr. Victor Horsley, the latest recruit to the ranks of that august body, has indeed proved a firebrand. He is a thoroughly earnest man, and believes that by judicious action on the part of the council the lot of the general practitioner can be rendered much more endurable than it appears to be at present. However, that this much-to-be-desired object may be achieved, Mr. Horsley contends that the members of the council must bestir themselves and take steps to insure that the existing regulations are fulfilled to the letter. *The Lancet*, while agreeing with Mr. Horsley that alterations in the methods of conducting medical affairs by the council would be highly beneficial to the profession at large, is still of the opinion that the present acts are not efficient to protect the medical profession, even if properly administered, but thinks that they require amendment before they can be made to do what is expected of them. Mr. Horsley is regarded as the champion of the general practitioner, and some little time ago broke a lance with Sir Richard Quain in defence of his cause. Now Mr. Brudenel Carter has taken up the gage, on behalf of the corporations and those prosperous members of the profession who are satisfied that things should remain as they are. As the London correspondent of the MEDICAL RECORD remarks, both gentlemen have been at issue in the General Council itself, and since then have descended into a more popular arena. At a meeting of the Southwest London Medical Society, Mr. Carter delivered a vigorous attack on the policy advocated by Mr. Horsley, but his speech was marred and its effect greatly diminished by personalities. In consequence of this and of Mr. Horsley's dignified reply, there can be no doubt that he has gained the first point. From the tenor of the correspondence which has flooded the pages of *The Lancet* for the last two or three weeks, it would appear that the majority of medical practitioners in England are on the side of Mr. Horsley and reform. Nevertheless it is extremely difficult for an outsider to pass judgment on the merits of the situation; the wisest plan will be to venture on no opinion, but merely to express the hope that the conclusion arrived at may be the one best calculated to benefit the greatest number.

Maisonneuve.—T. Chalmers Peebles, in an article entitled "A Cursory Visit to the Hospitals of Paris and a Near View of Some of Her Doctors in 1867" (*The Charlotte Medical Journal*, January, 1898), says: "M. Maisonneuve was also treating some cases of suppurating wounds of the extremities by suction. Stumps, after amputation, were inclosed with a rubber cap or cylinder, which was connected by a rubber tube to a pump, and as fast as the pus formed it was sucked into a glass jar. The students used to call Maisonneuve the 'butcher,' for at times he was very rough. On one occasion I saw him take hold of a young woman's forearm and shake the wrist-joint and hand violently until the ankyloses cracked and gave way, the patient screaming all the time. At another time he applied Chassaignac's écraseur to a hemorrhoidal tumor and proceeded without an anæsthetic; in the mean time the patient was suffering torture, while the surgeon only cursed his restlessness. I think in these two instances he justly earned his title."

[We should be slow in making accusations of cruelty against one who has done so much for the relief of suffering humanity, and should consider the time in which he lived.—ED.]

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended February 26, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Georgia, Griffin	February 23d	2	
Kentucky, Butler	February 8th to 24th	1

MEMORIAL ADDRESS ON JOSEPH O'DWYER, M.D.

BY W. P. NORTHRUP, M.D.,

AN ASSOCIATE OF SIXTEEN YEARS AT THE NEW YORK FOUNDLING HOSPITAL.

JOSEPH O'DWYER, M.D., the inventor of intubation, died at his home on Lexington Avenue, New York, January 7, 1898, in the fifty-seventh year of his age. He was born October 12, 1841, in Cleveland, Ohio; spent his boyhood near London, Canada, in which city he went to school; and took his first studies in medicine with Dr. Anderson. He began his lectures in the New York College of Physicians and Surgeons in 1864, graduating in 1866. Just at this time the staff of the Charity Hospital on Blackwell's Island was made a separate body, and as the result of competitive examination Dr. O'Dwyer took first place, and was thereby constituted sanitary superintendent of the institution. It was his duty to inspect the plumbing, the wards, the kitchen, and the food supplies. Dr. J. Lewis Smith was fond of saying to the younger men connected with the Foundling Hospital that he well remembered examining Dr. O'Dwyer for the staff appointment, and that he—O'Dwyer—passed an excellent examination. Among the internes were Dr. Le Roy M. Yale, Dr. F. A. Castle, and Dr. Peter Inches, now of St. John's, N. B. The visiting staff of the Charity Hospital was practically the same as that of Bellevue Hospital, and included Drs. J. Lewis Smith, A. L. Loomis, Austin Flint, Van Buren, L. A. Sayre, and Frank Hamilton.

A few cases of diarrhœal disease had been observed in the city but had not been recognized as cholera. One night a severe case of so-called cholera morbus was announced at the workhouse, was suspected, and was isolated. Fifteen days later sixteen persons came down with true cholera in one night, "and," to quote the words of one of the staff, "it came down the island pell-mell." Two hundred cases broke out in the workhouse. Dr. O'Dwyer, being sanitary superintendent, had charge of all arrangements for fighting the epidemic of cholera.

The fever hospital was located on the island, and to this were sent typhoid and typhus fever patients. During 1863-64, cases of typhus occurred sporadically in the city, and about the time of Dr. O'Dwyer's service cases broke out on the island and typhus became epidemic. Many before me remember that period, and the younger men are familiar with the marble slab of the lower lecture room, upon which were inscribed the names of the "ornaments" of the profession who succumbed to the fever while in discharge of their duty. Dr. O'Dwyer contracted the disease.

As sanitary inspector he had visited the workhouse on an urgent call, finding a patient early in the morning in the first onset of the disease. The patient was in a close, unventilated cell. Dr. O'Dwyer often said he knew the moment when he contracted the disease. It was while examining that man in that stuffy cell, before having had his breakfast. Promptly at the end of the usual period of incubation he was seized with the well-remembered pains in the head and back. Deliberately he finished his work, wrote out his wishes as to the disposal of his things, left letters for his friends, and went to bed. He remembered examining his eruption: assured that his case was a genuine one, he made his estimate of its severity, and shut his eyes to wait. Then followed days of which he could never give any account. His recovery was complete, without complications or sequelæ, and without impairment of any of his powers.

Dr. O'Dwyer chose what was called long service or full time on the staff, and the next we know of him (1868-69) he was examining physician of patients applying to the hospitals under the board of charities and corrections. He was examiner and distributor of patients, sending some to Bellevue, some to Charity. About this time also he opened an office with Dr. Warren Schoonover, on Second Avenue between Fifty-seventh and Fifty-sixth streets. He worked into a large practice in obstetrics, reaching ultimately the number of three thousand cases, including miscarriages.

In 1872, Dr. O'Dwyer moved to Lexington Avenue near Sixty-fifth Street, in close proximity to the New York Foundling Asylum, which had likewise moved up town and was about to open its new building (1873). Upon the new staff of this institution were Drs. Reynolds, J. Lewis Smith, and Joseph O'Dwyer.

From 1873 to 1880, tracheotomy was on trial in this institution, without a recovery. In 1880, Dr. O'Dwyer "began thinking" on croup, and some method for providing a channel through the larynx for the passage of air and secretions, without the complication of an open wound. How to hold apart the swollen false and true vocal cords till the disease should run its course, and the stenosis be thus relieved—this was his first thought. The most natural resource was a skeleton wire spring. This, however, soon gave way to a small bivalve speculum, formed on the model of a bivalve vaginal speculum. It was fitted with a spring to force the two valves asunder when placed in position. To keep the valves together during insertion, the introducer or handle curved on a right angle passed down through the hinged end, then through an eyelet on one valve; then, the valves being approximated, the pointed handle passed through a second eyelet on the other valve. Thus the valves were held close together until released by withdrawing the handle, when they sprang apart.[1] This laryngeal spring, or speculum, served to keep the air passages open, but had important faults. The interval between the open valves allowed the swollen mucous membrane to crowd in, and ultimately to cause stenosis again. It did not sink too low in the larynx, because of a rubber collar — gutta-percha dissolved in chloroform, applied layer on layer.

A great deal of experiment was required to get the spring of the proper strength. If too weak, it would not separate the blades; if too strong, it would cause ulceration from pressure. The mouth gag had not been devised at this time. The index finger of the

[1] Delivered at the New York Academy of Medicine, March 3, 1898.

left hand wore a shield in operations. It consisted of two metal discs, about the size of a silver quarter of a dollar, bent to fit the shape of the finger on the proximal phalanx, the dorsal and palmar discs being held together by rubber elastics.

The following is the first intubation recorded in the dead book of the New York Foundling Hospital:

"October 21, 1882, Dr. G. M. Swift, H. P——, female, aged four years. October 20th, severe croup; pseudo-membrane in pharynx; dyspnœa urgent, temporary asphyxia; relieved by introduction into larynx by Dr. O'Dwyer of one of his 'springs.'

"Eight hours later, spring having been removed, the child again became asphyxiated. The subsequent history is: treacheotomy, death.

"Autopsy: Pseudo-membrane in pharynx, larynx, trachea, and bronchi to finest bronchioles—continuous, tenacious, thickness of wet blotting-paper."

Third recorded intubation: "January 26, 1883. Diphtheria—larynx. Under chloroform, O'Dwyer, at 1:40 A.M., introduced his spring. Relief followed. In about ten minutes, after a cough, there was complete obstruction to respiration, and the child was apparently dead. Spring plugged with a piece of membrane, one and one-fourth inches long, the lower end being cylindrical. Removed; artificial respiration restored child. A larger spring, introduced seven hours later, gave relief. Five hours later the spring was removed, but immediately there were restlessness and cyanosis; spring reintroduced and dyspnœa relieved. Tracheotomy was refused by its mother, and the child died."

Thus far two points had been demonstrated: first, that the larynx would tolerate a tube; second, that air could gain entrance and the secretions find exit. Note that his only idea at first was to keep a channel temporarily open for the short distance between the false vocal cords and the beginning of the trachea. If this could be accomplished for five days, ordinarily the storm would have passed.

The bivalve laryngeal speculum or spring, with all its faults, had a recovery to its credit. This was the first operated case of membranous croup to terminate in recovery, in the thirteen years the Foundling Asylum had been in existence.

However, after three years of experience the idea of accomplishing the desired result with a bivalve laryngeal speculum was abandoned. With the instrument there was also difficulty in feeding, the same that so much embarrassed the success of later tubes.

About this time Dr. O'Dwyer learned of the work of Bouchut, of Paris, in tubage of the larynx. Nothing could induce him to inform himself fully on this man's work. All he knew was that the tube was like a thimble and was never pronounced a success. He resolutely shook his mind free, for he said that unless he worked out his own ideas alone that would be the end of his work. After some time, studying the larynx healthy and the larynx swollen and lined with pseudo-membrane, O'Dwyer appeared one day in the dead house with a new tube—a tube this time longer than the speculum, narrow, oval, or flattened laterally, having a collar at its upper end. To use his own description, it was "a tube of plain oval form, about an inch in length." The first mention of a "tube" occurs in a recorded history in the dead book, April 25, 1884. "Dr. O'Dwyer put in 'tube' at night; dyspnœa relieved; breathing fairly good till death, sixteen hours later."

In connection with this case a footnote to the history states that the question whether the lungs were in collapse or pneumonic was of much interest to O'Dwyer. He and Dr. J. H. Ripley, who had been for years very good friends, discussed at great length this question, Dr. Ripley contending that the lungs in such cases did not show pneumonia but collapse. One thing is certain—Dr. O'Dwyer was much pleased with the continued relief for sixteen hours afforded by this tube, and it was not coughed out.

The second trial with this tube resulted, after certain vicissitudes, in recovery. The patient was a girl, four years old. The tube was removed after sixty-seven hours, but required reinserting after five hours. The patient shut her teeth tightly upon the metallic shield upon the finger, and imprisoned the doctor until chloroform relaxed her jaws. The tube was then inserted, coughed out in three days, and not again required. This was the first recovery in intubation, and I may mention that about this time the name "intubation" was adopted for the operation. Here was a patient recovering from intubation. The next inquiry was, what would be the condition of the vocal cords? Would the voice return? Several weeks passed, and the child was aphonic. The cough, however, had an explosive quality which meant that the cord had not ulcerated away. The voice ultimately returned.

A new need was presented by this four-year-old patient—a mouth gag must be devised. The first gag was much like that now in use, except that the handles, or levers, were curved on a right angle, hanging down by the child's neck, and a clip, by gravity following along down as the levers approximated, held them together. The child in hitching up its shoulders occasionally dislodged the gag, and the modification made by Dr. Denhard, of continuing the handles out toward the ear and using a spring clip, was adopted and is still in use.

The pathologist at the Foundling Hospital during these years had many interesting friends about the autopsy table; many interesting discussions warmed that lugubrious underground cell. The autopsy book contains, for instance, two full pages devoted to the history of a case, with autopsy, the main points of controversy between Drs. O'Dwyer and Ripley, microscopic findings of the specimens, etc. It was the old discussion of pneumonia or collapse following croup and operation. This case was specially referred to me, as pathologist, to decide, Dr. Blodget, house physician, being witness to the points under discussion. Fortunately, this chosen case furnished abundant evidence of both collapse and beginning pneumonia, the verdict being confirmed by Dr. Delafield's examination, and the question was not settled. A little sidelight may be thrown upon this scene. Tracheotomy, of which Dr. Ripley was a great champion, was probably to have in intubation a competitor.

Difficulties were still to be met. This tube, for instance, which was retained and afforded relief, contained a little slit into which the extractor hooked in removing the tube. Into this likewise the mucous membrane hooked and held it fast, not without harm to the soft tissues when it was being removed—so the slit must be dispensed with. The tubes must be made longer to reach to the bifurcation. These, it was thought, would not be coughed out, and so they were not, because, having ridden up to the vault of the pharynx, they could go no farther, and an ever-present nurse could push one down again. Then came a second shoulder below the contact of the vocal cords—an abrupt shoulder above, a vanishing wedge below, the cords resting in the interval between the two shoulders. This tube remained too well; it was almost impossible to get it out, *i.e.*, to get the cord out of the groove. This was abandoned. Then came a long period of thinking, of measuring larynges, of modelling putty upon the middle of the tubes, and putting them into specimen larynges, of taking plaster casts. The result came at last in the form of the retaining-swell, which was a fusiform enlargement of

the middle portion of the tube lying within the trachea. Within the trachea was plenty of room. The cricoid ring (and this was rather an incidental discovery of Dr. O'Dwyer's) is the narrowest place in all the respiratory ways. These tubes caused pressure and ulceration at these places, at the base of the epiglottis, within the cricoid ring, and at the lower end of the tube. The epiglottic ulceration was obviated by giving the upper portion of the tube a backward curve, thickening and rounding the portion which pressed against the epiglottis in deglutition. The cricoid ulcers were difficult to overcome, and all final success depended on one thing. Unless a child could breathe through a tube much smaller in calibre than would seem possible at the first glance, intubation could never take its place as a successful operation. Here, consequently, began the process of thinning the tube's walls and reducing the calibre. After reducing pressure to the point of safety to the mucous membrane, it was found (what has been the marvel of every one viewing the tubes for the first time) that a child could breathe perfectly through an exceedingly small tube.

Few had occasion up to this time to reflect, I believe, as to how much motion the parts about the larynx take on in every act of swallowing. With the new tube held firmly in the larynx and cricoid ring, every act of swallowing pressed the tongue hard down upon the epiglottis, and it upon the tube's head; at the same time the lower end of the tube rode up and down for half an inch upon the mucous membrane, and, with the early tubes, dug its way in, leaving bare the tracheal rings. To obviate these drawbacks, the lower extremity was thickened and rounded into a smooth knob. Let us bear in mind that the backward curve, the blunt rounded head of such odd shape, the knobbed lower end, with the thin-walled, laterally compressed upper end (of the tube) were the results of long painstaking study and experiment, measurements and casts, trials of models, changing and changing for six years.

The earliest specula, springs, and tubes were made by a German, far down town, who was clever enough in his way, but his way was troublesome. To meet him O'Dwyer had to go to his shop, when, finding it vacant, he would hunt the nearest gardens and saloons. Sooner or later he would find him and sit by him till the work was done. He was the only man who he knew would do what he wanted and do it in his way. Later he had better fortune in the instrument maker he employed for years, and who alone still continues to make O'Dwyer's tubes—that is, tubes as he wished them.

After all the six years of thinking, trying, and changing, what happened the moment the tubes were put before the public? There was no patent to restrain any maker. He could make O'Dwyer's tubes, as many as he liked; and never a maker who looked at them admitted for a moment but that he could make them—yes, make them exactly, just a copy of them, faithful to the model. What did these complacent makers do? They never took a thought of such a thing as a backward curve. As for the head being that odd shape, what difference if they make it a trifle more simple? Even the rounding of the edges did not appeal to them. As for the swell, that was satisfactory; and the lower end of the tube—why, they left it sharp. At O'Dwyer's request, I picked up in London and different places samples of tubes that their best makers were selling, and tubes made from models sent out from New York with O'Dwyer's approval. They were a travesty. They embodied every vice. There was only one way they could be made worse, and that was by indenting the cutting edges like a buzz saw. They would be ludicrous, were they not cruel. The English made the worst possible intubation instruments. Little wonder they were not pleased with their first results. This was to O'Dwyer one of his secret grievances in life. "Bad tubes!" he would say; "bad tubes!"

The perfect intubation tube of to-day is made of hard rubber. Upon it lime salts do not form to tear the mucous membrane; it does not corrode, does not require replating; it is boiled and disinfected with the utmost freedom; it can be worn indefinitely without removal. The hard-rubber tube, children's size, is the latest improvement from the hand of the inventor—O'Dwyer.

Difficulty in feeding was one of the great drawbacks to the success of intubation. Diphtheria patients must be fed these five days of tube wearing. Finally, the Casselberry method was a great relief. Dr. Casselberry, of Chicago, fed a patient who had lost his epiglottis through tuberculosis, by making him swallow up hill. If fluids entered the trachea, they instantly gravitated out. This method he applied to intubated patients, with great joy to Dr. O'Dwyer.

Two years after intubation was given out fully to the public, and half a year after the first ovation to its inventor at the International Medical Congress in Washington,[1] Mrs. O'Dwyer died. For those who knew the man, it is not difficult to understand how much he needed all that is comprehended in the word "home." He was a retiring man, of few words; always thinking, sensitive, conscientious, diffident. If any near friends were asked what was the one thing most necessary to a man of Dr. O'Dwyer's disposition for his contentment and happiness in life, the answer would be, "A congenial home atmosphere." If asked what kind of a wife was required to produce such congeniality, they would say one who was hopeful, sympathetic, encouraging. If we add to these qualities beauty and absolute devotion, we have a fair picture of Dr. O'Dwyer's chosen companion. No published report on intubation, no fleeting gossip, no current views and criticisms escaped her. No friend who called ever missed an opportunity of telling Mrs. O'Dwyer any favorable experience or report on intubation. To see her drink it in, to see her handsome face and eyes light up, were ample recompense for a little trouble. Equally entertaining was the doctor's quiet chuckle and remonstrance. Her visit to Washington, when intubation had its first ovation, at the International Medical Congress, was an occasion of the highest degree of wifely pride and rejoicing.

Dr. O'Dwyer was a poor sleeper from the time he began thinking on intubation. The thoughts of the day clung to his brain at night, and sleep was at first broken, and at length absent, for the greater part of consecutive nights. After the death of his wife followed the years in which intubation became popular in New York, and his doorbell rang much at night. Even though he did not go out, he could not sleep again. Once a tube was inserted in a child's larynx, his anxieties began. The operation was new; the accidents were all reported to him from the whole world. These worried him. Not to dwell too long upon the subject, his whole tranquillity of mind was destroyed, and sleep was gained only with greatest difficulty. Another point I wish to make is that with all this struggle to sleep, and frequent recourse to sleeping-medicines, he never was bound by any drug habit. To my mind, watching him as I have for months and years, the strength of character shown in this respect is unequalled by any other example. Intubation de-

[1] Referring to the above, I have received the following:

"DEAR DOCTOR: You made a mistake which you will be glad to correct, in speaking of the "first ovation to Dr. O'Dwyer at the International Congress of Washington." The first public appreciation of his work, amounting to an ovation, was that of the State Medical Society, February, 1887.

"Very sincerely yours,

"A. JACOBI."

stroyed his ability for good sleep, it broke his health, it made him prematurely old.

If I were asked what was the chief characteristic of Dr. O'Dwyer's medical excellence, I should say his habit of thinking and his good logic. He had a good medical mind, good medical judgment—that quality which allows a man to grow after the age of forty. Physiological subjects connected with respiration interested him much. Why a lung expands after an empyema is operated upon was one of his night cogitations. He was a man of few words, but a short conversation with him was sure to set one thinking. He wanted to ask everybody some question—if a laryngologist, he had numerous questions; if a neurologist, orthopædist, ophthalmologist, he had questions for all. Some question had come to him in the night, or in the street car, and he saved it until by chance he met the specialist who could answer it. In later years his vision was not good and he read less. Again he was reduced to thinking. He was a recluse, and reflection was his refuge.

To the New York Foundling Hospital, with which he was connected for twenty-five years, Dr. O'Dwyer was everything. To the maternity service he was the expert obstetrician; in intubation, he was the teacher; in general service, his was the constant consulting mind; to the Sisters of Charity, he was the physician, the friend, the general regulator of the household. All adored him.

Few know that Dr. O'Dwyer had attended three thousand confinements. Dr. Henry Blodget, one of our internes, who had taken a special and extended course in obstetrics in Vienna, one day exclaimed: "In his own way Dr. O'Dwyer has come to practically the same methods and results as those of my Vienna teachers, and there's nothing he has not seen!"

Of Dr. O'Dwyer's last illness, Mr. President, I have not the heart to write. He longed for sympathy and friendly encouragement, and so would be pleased with this meeting; but the one paper which he would beg to have suppressed is the one to which you are now listening. As to the rest of the papers, they would be a pride to his boys.

In his early life Dr. O'Dwyer was taken with pulmonary hemorrhage. For three years he lived in the woods of Michigan, a member of a surveying-party, and ever since counted himself a case of consumption cured. For several years he had been rather feeble. His walk suggested effort. In the morning he was languid and dull. His only good sleep came to him about the time that early callers were liable to pull his bell. He was fatigued easily, and had but little resiliency. With all this sleeplessness, languor, and easy fatigue, reflect upon his record of things accomplished! Thinking was left to him, even when his eyes weakened.

Whatever forces wrought it, whether a combination of physical weakness, the mellowing influences of religion, the chastening of affliction, and the constant devotion to his motherless boys, Dr. O'Dwyer's was the most godlike character I have ever seen in man. There was an abundance of spirit. He could be very angry—a sort of justified indignation—but this feeling found only temperate expression. He was ambitious, but scrupulously careful to recognize the contributions of others. His ambitions were, after all, largely to have his boys think well of his achievements.

O'Dwyer was as peculiarly sensitive to every criticism on intubation as though it were his bride or his baby. It worried him that such imperfect and cruel instruments should be made and sold. The unfavorable criticisms when intubation was first made public cut him to the heart. They were much of this manner: "The larynx will not tolerate a tube" or "a foreign body; the calibre is too small; it will drop into the trachea; it will become plugged." Medical men had many inspirations concerning the dangers. Strange to say, they all thought the operation easy—any one could do it. Then came modifications, so-called "improvements." Every green graduate saw improvements at once. These improvements promptly appeared in print, with a cut and the name of the callow youth. Then the instrument makers made tubes. They made them cheap. Why? It was obvious to them that they could be cast in a solid piece, not made in halves and put together. They smiled in a superior manner at the tilting back of the head; they improved its shape, they took little thought of the retaining-swell, and overlooked entirely the knobbing of the lower end. Their tubes fitted the larynx much as false teeth would be expected to fit the œsophagus.

Mr. President, and friends who really knew Dr. O'Dwyer, I am speaking for you. Hear me, and witness. What the world knows of this man are his genius as an inventor, his achievement in adding to the equipment of the profession a great operation; he made the most conspicuous real contribution to medical progress within fifty years. That the world knows, that the world has acknowledged. To us there is another and a pleasant duty—to testify that with this genius there was all that goes to make a man. His home life, his religious life, his civic life, his professional relations to colleague and patient, his hospital relations were such as befit a high-principled man. Wherever he moved in the daily routine of life, he left little groups who delight to tell of O'Dwyer the man. Those of us who were accustomed to go to him for advice, or those who wished simply to be in his presence for the nameless pleasant influence of his personality, have lost a part of our lives; there is left to us a daily-recurring impulse, as to one in a light sleep, to rise up and seek him out. Finally, highly as we here present, all friends of this good and great man, highly as we esteem him as an inventor and genius, highly as we rate him as a practitioner of wide knowledge, much as we valued his superior medical judgment, there is one feature we would place high above this all. We would write upon his monument his achievements, his general knowledge, his medical judgment, but above them all we would write: "O'Dwyer, the Man."

EXTRAGENITAL LESIONS OF SYPHILIS.[1]

By CHARLES F. BEVAN, M.D.,

PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

The intensely infectious nature of the poison of syphilis, the very extensive territory over which this malady extends, are always of interest; but so thoroughly established are the cardinal facts relating thereto that additional evidence may be considered unnecessary. We all agree that as a venereal disorder syphilis is widespread. We rarely dispute the belief that the chancre or initial lesion both marks the beginning of the malady and is very frequently the chief source from which the infectious material is disseminated. The recognition of the initial lesion is but too frequently mistaken; not until some of the pronounced secondaries have appeared, not until many opportunities for infecting the innocent have occurred, do we make the correct diagnosis and institute precautions for the protection of the innocent. This delay in diagnosis is not because of inherent difficulties, but merely because our attention is seldom directed

[1] Read at the semiannual meeting of the Medico-Chirurgical Faculty of Maryland, at Ocean City, Md., September 16, 1897.

to the fact that, no matter where the initial starts, it will still preserve its dominant traits. When it is located on or about the genitals we almost intuitively begin the differentiating process, while when it is encountered in exceptional localities we seem to act with the reserve meted out to a new acquaintance. The points for diagnosis here as elsewhere are the same. An ulcer is by far the most common lesion, though a moist papule is often seen, or the sore may present as a mass of fungoid granulations. The amount of secretion is rarely great; infection with the staphylococcus or streptococcus sometimes impresses more destructive features upon the local ulceration than is normal, and may lend thereby an element of some uncertainty. This point was well marked in one of the following cases, in which the lesion was located upon the lip. Microscopic examination of the secretions will be of aid in suggesting the requisite local treatment appropriate. Induration of the sore is rarely wanting; it may be but slight in some cases, especially the moist papules, but its entire and complete absence I have rarely seen. Generally the degree of hardness is sufficiently marked to form a special feature. The nearest lymphatic glands are those most frequently found enlarged. When the lesion is upon the face I have found the glandular disturbance very decided, often unsightly, causing more distress of mind to the patient than the sore itself. Deductions as to the nature of the sore dependent upon the incubative period, while of great value when the lesion is genital in location, are seldom of service with the extragenital lesions, owing to the difficulty in locating the time, mode, or manner of infection. Attention to the sore, its induration, scanty secretion, and associate glandular involvement furnish the necessary data.

Treatment.—It seems to me best to delay the administration of mercury until after the cutaneous eruptions are positive. Undoubtedly, however, this rule can often be violated advantageously, and should be when the lesion is menacing to the interest of others; and yet even in such cases it is best to suspend this drug just as soon as the local sore has been brought under control. Black wash, after the sore has been carefully cleansed as for surgical work, has given me more satisfaction than have any and all other topical applications. Nitrate of silver is often serviceable. The dry powders, taking up some of the secretions, will at times assist in comforting the patient.

Case I.—Chancre of finger. I. T. W——, a physician of rather irregular habits, aged forty-seven years, was referred to me by my colleague, the late Prof. O. I. Coskery, November, 1879. He had been annoyed for five or six weeks by a sore on the left index finger. Examination showed an ulcerated surface, secreting but little, not specially painful, and surrounded by a decided area of induration. Lymphatic enlargement of cubital, axillary, and postcervical glands was well marked. The doctor stated that under the impression that the sore finger was a mere "runaround" he had poulticed it for days, without relief; that he then considered the trouble to be the result of some local poisoning, and had cauterized it freely, following this with poultices. When Dr. Coskery first saw the case he believed it due to a post-mortem infection, and had on two occasions thoroughly cauterized it, but as improvement did not take place he had referred the case to me. The patient on being questioned recalled an attendance upon a syphilitic woman who aborted at three and one-half months some three weeks prior to the development of his sore finger. She at that time had vulvar condylomata and other lesions. The diagnosis of syphilis was one he was unwilling to accept. In a few weeks an extensive pustular syphilide appeared, followed by mucous plaques in the throat and mouth. Mercury was liberally used with great benefit, the local sore healing' eruption and patches disappearing. His irregular, dissipated habits favored a malignant type of syphilis, and in eighteen months a severe sore in his mouth was followed by perforation of the hard palate. He died in 1883 from some brain and visceral troubles, probably syphilitic, for he had abandoned practice and removed from this city.

Case II.—Chancre of lip. G. A. C——, aged twenty-four years, a variety actor, was seen May 2, 1882. He complained of a sore located on the lower lip, which had been there for about four weeks. Sore greatly indurated and but slightly ulcerated; sublingual and submaxillary glands much enlarged. When the nature of the lesion had been explained to him, he accounted for it by stating that one of the girls in the troupe with which he was engaged had some kind of rash on her face and body, and that he frequently kissed her. On examination of the girl a papular syphilide was found over her body, with mucous patches on the tongue and the side of the mouth. Within a few weeks the usual secondary eruptions, followed by loss of hair, sore throat, etc., developed. Under a careful treatment the disease was brought under control. The patient followed up his treatment for four years, then married, and has suffered no bad results. He was seen and examined in 1894.

Case III.—Chancre of nipple. Mary W——, aged thirty years, consulted me for a sore located on the right nipple, August 9, 1885. She attributed the sore to the bite of a mosquito. The sore in question was on the side and base of the nipple, ulcerating in type, secreting feebly, decidedly indurated, with great glandular enlargement—mammary, axillary, and postcervical. It had been first noticed in the early part of July. After the nature of the sore had been explained to her she admitted that a young man to whom she was betrothed had taken some liberties with her, and had several times sucked her nipples. She brought him to see me. In his mouth were mucous patches and a typical pustular syphilide was over his body. In October a macular eruption, with loss of hair and eyebrows, appeared. She was married in January and in May aborted a three-months' fœtus.

Case IV.—Chancre of nipple. Mary C. B——, aged twenty-two years, single, was employed at the Nursery and Child's Hospital as a wet-nurse. According to her statement her family history was good. She had never suffered from any severe illness and was of robust physique. She was confined with an illegitimate child on August 10, 1887. Three weeks later, after careful examination, she was received into the nursery as a wet-nurse, but a foster child was not given her until September 15th, at which time a newly born babe, apparently but a few days old and in perfect health, was assigned her. She was advised to nurse her own child always from one breast and give the other to the foster child, which she did. On December 7th, she complained of some soreness of the nipple used by her foster baby. A small superficial excoriation was noticed along the side and base of the nipple; its appearance was that of a moist papule, and some simple ointment was ordered her. December 16th, she complained of increased soreness in that breast; the axillary glands were found enlarged, sensitive, and stony hard; the sore upon the nipple had extended somewhat and had become thoroughly indurated. General lymphatic enlargement was now made out. General pustular syphilide developed in February. Careful examination of the foster child was now made, which resulted in the finding of several mucous patches on the side of the tongue and buccal membrane; the buttocks, too, were chafed and excoriated. The child was placed upon Gray powder. Black wash was ordered for the mouth, and in a few days some

improvement began; the amount of change in nutrition was unsatisfactory. In February the mother was placed upon a rigid mercurial course, with rapid improvement and disappearance of all active symptoms. The foster child died in May, from meningitis syphilitica. Her own child remained free from all signs of the disease; it was seen some two years later and was still free from all evidences, though the mother had suffered from sore mouth and an attack of iritis after leaving the institution.

Case V.—Chancre of anus. F. H. W——, aged thirty-two years, single, of spare build, consulted me for supposed hemorrhoids, November 7, 1890. Family and previous history unimportant. On examination I found an ulcerated sore involving the external sphincter, area around sore indurated, some mucopurulent secretion, sphincter rather relaxed, and anal orifice patulous. The trouble was regarded as an irritable fissure. The patient had been complaining of this rectal disturbance for over two weeks. A simple ointment was ordered and he was directed to report on November 10th. At this time the condition of the sore showed more decided induration; the inguinal glands of both sides (unnoticed at the first visit) were enlarged, movable, non-adherent, and stony hard. November 15th, the glandular enlargement was more decided and could be now classed as general; there was no improvement in the local sore; over the abdomen a slight macular eruption could be made out. November 20th, eruption decided and general. Some soreness of the throat was complained of, due to tonsillar patches. The patient was now placed upon proto-iodide-of-mercury pills, one-fourth of a grain, the dose increasing rapidly. December 1st, decided improvement. January 3, 1891, anal sore healed, body free from eruptions; hair falling out: an occasional mucous patch about the mouth the only annoyance. After a rigid cross-examination the patient confessed that he had for several years been in the habit of indulging in abnormal sexual relations; that even since he had been under my care he had indulged in the bestial practice.

Case VI.—Chancre of lower lip. J. H——, colored, female, married. Entered City Hospital, August 30, 1892; was discharged, October 24, 1892. Family history negative; previous history good. Husband healthy. About the 1st of July, the patient says, she struck her lip against the mantelpiece. There was an ulcer in the left corner of the mouth and lower lip, nearly two inches across externally. Base decidedly indurated; secretion from ulcer not very great. Submaxillary, suprahyoidean, and general cervical glands greatly enlarged and of stony hardness. Local treatment with antiseptics, etc., then with the black wash soon brought the ulcer into a healthy condition of granulation. October 7th, a pustular syphilide was made out over the trunk and extremities. She was then placed upon a mercurial course (inunctions). An operation was attempted, looking toward the restoration of the lip, but resulted in only a partial success, owing to the low vitality of the tissues. Granulations, however, closed the wound. She was supplied with medicines and ordered to continue treatment. She reported in January, at which time she was found to be about seven months advanced in pregnancy. She was delivered of a child at term. The child when seen last (one month old) did not show traces of syphilis. The mercurial treatment had been faithfully attended to from October. No definite information could be secured as to the source of actual infection.

Case VII.—Chancre of hard palate. Stella H——, aged twenty years, single; common prostitute; mother of a child now nine months old. Applied for treatment at City Hospital, November 5, 1892. Family history negative. She stated that about one week ago a small sore, which had become so painful as to interfere with her eating, had made its appearance in the roof of her mouth. An indurated sore, about the size of a ten-cent piece, was found about the middle of the hard palate. No genital lesions could be made out. The auricular and anterior cervical glands were enlarged. We learned that this patient was known as a common "sucker." She claimed that a man with a sore mouth stuck his tongue in her mouth during intercourse. Black wash was ordered. She reported again about Christmas, with a coppery-colored eruption over the chest and abdomen, buccal mucous patches, etc., and was then placed upon proto-iodide of mercury. She reported again in July, laboring under the effects of a miscarriage at the fourth month. She had syphilitic condylomata around the anus and labia, with laryngeal lesions, and was placed under rigid treatment. In April, 1895, she was seen again and seemed free from all active symptoms.

Case VIII.—Chancre of tongue. George H. B——, aged thirty-two years, civil engineer; consulted me, November 5, 1893. He had always enjoyed the best of health (a statement more than corroborated by his appearance); had had gonorrhœa five years before. He claimed that the sore tongue for which he consulted me began in the last week of August. Examination showed an ulcerated sore on the left side of the tongue, one and one-half inches internal to the tip, about the size of a nickel. The sore was much indurated; the submaxillary, sublingual, and suprahyoidean glands were greatly enlarged. On his body there was a decided pustular syphilide; the hair and eyebrows were falling out, etc. The nature of his disease was carefully explained to him in detail. He accounted for the lesion as one contracted by smoking a pipe belonging to a friend who had been camping with him during the summer. His friend had syphilis. He was placed upon constitutional treatment, which he carried out faithfully. When last seen, January, 1896, he had no active trouble, and was still continuing treatment.

Case IX.—Chancre of lip. C. O——, aged twenty-two years; white: prostitute by occupation. Admitted to City Hospital, June 29, 1893; discharged, October 21, 1893. In April, 1893, her upper lip became chapped; some time afterward she noticed a marked hardness about the fissured lip, which increased the swelling and deformity until she came to the hospital. When she was examined, on the left side of the upper lip an ulcerated sore, about the size of a dime, was found. Its edges were prominent, hard, with scanty secretion; there was submaxillary, cervical, and epitrochlear glandular enlargement; a coppery-colored papular syphilide existed over the trunk and extremities. She was in the third month of pregnancy. The patient was placed upon proto-iodide of mercury; locally black wash was used. Under this treatment the ulcer healed rapidly and the eruption disappeared. She was sent to the Maternity Hospital, October 21st. Her child died in April, from a syphilitic meningitis. The mother, under continuous treatment, has shown no recent symptoms. No history as to the mode of infection could be made out.

Case X.—Chancre on hand. John T——, aged twenty-two years, laborer. Admitted to City Hospital, September 21, 1894; discharged, November 22, 1894. Previous history good. Present condition: Lungs, heart, kidneys, and general condition show an excellent state of health. No marks of syphilis about the body except the sore hand. At the base of the middle finger of the right hand is an ulcer, one-half inch in diameter, slightly elevated, with thoroughly indurated base, ending abruptly in the surrounding tissue; there is only slight secretion. Epitrochlear and axillary

glands enlarged. This sore had existed since August 21st, and was believed to have been produced by striking a man in the mouth. October 1st, several sores, mucous patches, were found in the mouth. October 5th, a diffuse roseola appeared on the back and abdomen. The patient was placed upon one-fourth of a grain of proto-iodide of mercury three times daily, the dose being increased till physiological symptoms were induced, and then this drug was continued in reduced doses. November 15th, the sore on the hand had healed and all other lesions disappeared. He was discharged on November 22d, but was at once employed in hospital work and so remained under treatment and observation until February, 1895. No further syphilitic lesions developed.

Case XI.—Chancre of lower lip. W. F. M——, white, aged thirty years, widower. Admitted to City Hospital, February 2, 1894; discharged, April 15, 1894. Family and previous history good. Without any assignable cause, he says, the sore upon his lip made its appearance some two months ago (December, 1893). When admitted to the hospital the patient had an ulcerated sore upon the left side of the lower lip, about three-fourths of an inch in diameter. It had only a scanty secretion, was indurated and cartilage-like in its feel, and ended abruptly. The glands of the left side, submaxillary and suprahyoidean, were particularly enlarged, though a general glandular enlargement existed, and a macular syphilide over the entire body. The patient had been living with a prostitute for over two months. He said she had had a sore mouth and objected to his kissing her. Mercurial inunctions were prescribed. March 1st, one-fourth of a grain of proto-iodide six times each day was ordered; much improvement. March 31st, ulcer healed; mucous patch on inner surface of lip. April 15th, no lesions. Discharged.

Case XII.—Chancre of lower lip. James G. W——, aged twenty-five years, single. Applied for aid at the dispensary of the College of Physicians and Surgeons, July 10, 1895. Patient had been spending some two weeks in the camp of the State militia and had used the camp drinking-cup. Ten days after returning home an ulcer, the size of a dime, appeared on the margin of the lower lip. The surface was covered with a slight purulent discharge. The lymphatics were much enlarged, especially the submaxillary of the affected side. The ulcer was moderately indurated. No signs of syphilis could be made out on any other part of the body. The sore was treated simply pending the evolution of secondary symptoms. The patient transferred his attentions to a neighboring hospital, from which source we learned that in August pronounced constitutional symptoms of syphilis had occurred.

Case XIII.—Chancre of upper lip. Henry G——, aged twenty years, applied for treatment at the dispensary of the College of Physicians and Surgeons, February 27, 1895. For the past six months the patient had been keeping company with a prostitute, who had, according to his statement, an eruption on her body and a sore mouth. One month ago (January, 1895) a sore appeared on the margin of the upper lip, and one week ago a sore was noticed on the lower lip. Present condition: Patient is in good health save for his local condition. There is an indurated sore on the upper lip, the size of a copper cent. Similarly located on the lower lip, there is a sore not quite so large, not indurated, which he says came from a chap. Cervical and auricular lymphatics enlarged. No eruptions or lesions on mucous surfaces; genitals show no lesions. Sores upon both lips, covered with purulent secretion. Patient was ordered black wash for the sores but no constitutional treatment, and to report in one week, which he failed to do. He was seen at his home three weeks later, suffering from marked secondary symptoms, mucous patches, and a papular syphilide. At this same visit his mistress was examined, and found to have mucous patches in the throat and on her lips. Both were placed upon constitutional treatment, given advice as to the contagious nature of their maladies, and urged to continue treatment. They failed to report for further advice.

Case XIV.—Chancre of face. William R——, aged twenty-one, single. Applied for treatment at the dispensary, March 20, 1897. Family history negative. Previous history: Had gonorrhœa last October, and was now suffering from posterior urethritis. On the night of December 7, 1896, the patient slept with a prostitute who had been treated at the City Hospital for syphilis. At this time the patient had a small pimple on the left side of his face, which the woman bit and sucked. Three weeks after this he consulted a doctor for this sore, which was then about as large as a dime, very hard, and was discharging a small amount of pus. The sore did not improve, so on March 20th he applied at the dispensary. The sore at this time was one inch in diameter, greatly indurated, red, and covered with granulations. Submaxillary and cervical glands much enlarged; mucous patches in mouth; falling of hair; a papulo-squamous syphilide over the body. He was placed upon mercurial inunctions and proto-iodide pills. Improvement was decided. The sore on the face was soundly healed by May 10th, though a deep red spot marks the site of it. May 28th, the body was free from all signs of active syphilis.

Case XV.—Chancre of tongue. Sarah S——, aged thirty, dressmaker, single. Admitted to City Hospital, February 19, 1897. Family history negative. Previous history: Six or seven years ago was treated for gastritis; two years ago had nervous prostration. In December, 1896, developed rheumatism, for which she was treated at the City Hospital; was discharged February 12th, and was readmitted February 19th, complaining of a sore on the left side of her tongue. The patient said she noticed this soreness of her tongue before she was discharged, but supposed it was due to her medicines. Present condition: On the left side of the tongue is a single sore the size of a nickel, decidedly indurated, with little or no secretion; the submaxillary, sublingual, suprahyoidean, and cervical glands are enlarged. Over the chest, back, and inner side of the arms and thighs is a decided papular syphilide. She states she used the same drinking-vessel and towel used by a syphilitic patient who occupied the bed adjoining her own. She denies all sexual relations, cannot recall kissing any one, nor can she give any clew to the source of contagion, save that of the syphilitic above alluded to. Under rigorous constitutional treatment all lesions disappeared. She is still under treatment.

Case XVI.—Chancre of lower lip. Mary E——, housewife, married, aged thirty, mother of three healthy children. Previous history negative. Came to dispensary of college February 12, 1897, with the following history and symptoms: Her husband had for some time past been treated for a sore mouth. About the last of January the patient noticed a swelling on the lower lip, which had been getting larger, had ulcerated, and from which there was but little pain. Present appearance: On the right side of the lower lip near the angle of the mouth is a somewhat elevated, moderately indurated, circumscribed sore, one-half inch by one-fourth inch in diameter, with brownish-red, polished, clean, ulcerated surface. On the corresponding side the sublingual and submaxillary glands are much swollen, round, and hard; the cervical glands are involved to a slight extent. The buccal mucous membranes, etc., are normal. Her husband was seen and examined. On the buccal mucous membrane and tonsils were numerous patches; over

the abdomen was a fading macular syphilide. There was general glandular enlargement. Owing to the great cosmetic defect and the danger of infection to others, she was at once placed upon strict constitutional treatment. In ten days the sore was covered with epithelium, induration was much less, and glandular enlargement was reduced, when treatment was discontinued to await development of secondaries. After a month's delay it was learned that she was about two months pregnant, so constitutional treatment was again pushed. On June 5th the patient's appearance was about normal; there were a small mucous patch on the hard palate, some huskiness of voice, etc. Treatment was ordered to be continued. She reported the last week of August that she had stopped all medicine and had miscarried. A general pustular syphilide covered her body, and there were mucous patches in the mouth, much loss of hair, and marked physical debility. She is now under active treatment.

Case XVII.—Chancre of thigh. Kate M——, aged two years, was brought to the dispensary of the College of Physicians and Surgeons, November, 1896. Family and previous history negative. On the inner side of the left thigh, upper part, was a clean-cut ulcer, three-fourths inch in diameter; the sore was thoroughly indurated, cartilage-like, and secreted but little pus. The inguinal glands were stony hard, and enlarged on both sides, but more markedly on the left. A papulo-squamous syphilide was found over the trunk, back, and extremities. The mother has two other children, both healthy. She herself showed no evidences of syphilis. She told us the sore upon the thigh was of more than two months' duration: that the eruption over the child's body was of one week's only. No positive mode of infection could be made out. Treatment was ordered. The child never reported again, and when looked up could not be found.

The location of these seventeen lesions, summarized, were: Anus, 1; cheek, 1; fingers, 2; lip, upper, 5; lip, lower, 2; hard palate, 1; nipple, 2; tongue, 2; thigh, 1; total, 17. The consideration of these and similar cases occurring in the practice of almost every physician raises at once a most important question, viz.: Can anything be done by us in our capacity as physicians which may prevent, or, failing that, minimize the spread of this and similar affections? The first duty of the physician should be to disseminate knowledge — to his patients as regards any special lesion he may have; to the public at large as regards the nature, manner, and mode of infection of this as well as of all other infectious disorders. There is a rather widely spread belief among the laity that only the initial lesion of syphilis is capable of producing that disease; that when once this sore has disappeared, not only are the victims not liable to distribute their disease, but that they are absolutely well. If, while the initial lesion is present, some form of mercury has been administered to them, the usual delay in development of the secondary phenomena dependent thereon often induces the conviction that they have never had the disease. Indeed, I have seen a number of medical men who rejected their first carefully made diagnosis, only on account of the fact that the secondary phenomena had not developed within the time limit expected by them. Such patients, lulled to fancied security, become dangerous in the extreme to the innocent as well as to themselves. It is upon this class that the essential facts pertaining to the contagious lesions of syphilis should be firmly impressed. No half-way views should be tolerated. The truth, even with its horrors as we physicians see them, should be made a subject of general information. The community at large has always shown, as is but natural, the greatest desire to escape disease, and by wise legislation to avoid or reduce to a minimum the chances for its contraction whenever the dangers and facts pertaining to it have been carefully brought to its notice. The spreading of knowledge concerning syphilis and venereal disorders has been opposed by most of the rigid moralists and clerical classes, rather, I desire to believe, from ignorance of the essential facts, than from any hope of ever freeing humanity by any system of morals. They do not believe in giving such protection and countenance to immorality as belongs to a well-regulated licensing-system, because they labor under the belief that these disorders are invariably contracted in a venereal manner. While we cannot but admit the greater frequency of their venereal dissemination, we must not fail to impress upon all that there are other modes; that the innocent are often accidentally infected and become agents for the scattering of this social pest. These cases, just reported, are indeed valueless, if they fail to impress one with this deduction.

No matter how rigid our moral ideas may be upon the subject of licensing prostitution, we must not allow prejudice to obscure facts. We must recognize the sexual passion as one of the strongest impulses of our nature; that wherever men and women cohabit promiscuously there will be found the whole class of venereal maladies, and that some of the innocent must fall victims to the prevailing disorders. To protect and save even the few is an imperative duty. The regulation of prostitution by law is neither new nor yet an untried experiment. In 1863 the experiment was made at Nashville, Tenn. Medical Director Gihon, of the United States navy, reports that the amount of venereal disease was markedly lessened: that the women, who at first were rebellious, not only became quite reconciled to the system, but often voluntarily came to the hospital for examination for suspected disease. In 1872 the legislature of Missouri passed a law requiring registration of prostitutes and medical examinations at regular intervals. When found diseased they were sent to and retained in a hospital until they were cured. Under this system the number of prostitutes as well as the amount of venereal disease decreased. In the *Medical News* of June 12, 1897, Assistant Surgeon Crandall calls attention to the impairment of the United States naval service through the prevalence of venereal disorders. In the London *Lancet* of January 30, 1897, the condition of the army in India since the repeal of the "cantonments acts," relating to the medical inspection of prostitutes, is vividly shown. More than one-third of the entire army is reported invalided from venereal disorders, and fully one-half of the army is unfit for marching-service.

So long as human nature remains unchanged, so long will venereal maladies exist. The sexual appetite must and will be gratified; it is devoid of a conscience. Wise legislation and the regulation of prostitution by license have afforded protection to many, have improved the morals of the community, and have afforded the means through which many prostitutes have been redeemed and have been restored to lives of usefulness.

857 Cathedral Street.

Gastro-Intestinal Antisepsis.—At present we are groping in the experimental stage. The list of so-called antiseptics is all but unending. Successes are not so common as failures, and yet enough has been accomplished to warrant still greater effort. The way to fame through the field of bacteriology, like the maddening rush for wealth along the mighty Yukon, must, expectedly, be impeded by error, disappointment, and failure; but neither individual error, disappointment, nor failure can stay the onward march or detract from those who succeed.—Dr. A. J. Pedlar.

THE NON-RECOGNITION AND ERRONEOUS DIAGNOSIS OF LOCOMOTOR ATAXIA.[1]

By WILLIAM M. LESZYNSKY, M.D.,

LECTURER ON MENTAL AND NERVOUS DISEASE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

THE pathological process underlying the disease known as "locomotor ataxia" is a parenchymatous degeneration terminating in sclerosis, which principally involves the sensory neurons. The peripheral motor neurons are also frequently implicated. In other words, it may be looked upon as a degenerative disease affecting various parts of the entire nervous system, while the most pronounced and extensive lesion is found in the posterior columns of the spinal cord. The morbid process may attack the cranial nerves and their nuclei as well as the peripheral nerves in the extremities. The brain cortex does not always escape. In the vast majority of cases there is an antecedent history of syphilitic infection. It is therefore considered by many as a metasyphilitic process, *i.e.*, a sequel of syphilis. The time of life at which it usually appears is between thirty and fifty years of age, affecting males oftener than females. The disease is insidious in its origin and slow in its progress. These facts although briefly mentioned are of much diagnostic value.

The appearance of a classical case of the well-advanced disease, as described in the text-books, is familiar to all. When such a case has once been seen it will always be remembered, and therefore requires no special description here. There is a superabundance of convincing proof to establish the fact that this, probably the commonest form of organic nervous disorder, often remains unrecognized for months or years during its early stages, although ample evidence of its presence may be discoverable by proper methods of investigation. To the most sanguine neurological mind the approach of the medical millennium does not imply the restoration to life and normal function of sclerosed and destroyed nerve structures; but, if our modern therapeutic methods are to prove curative in this disease, they must be utilized before organic changes are too far advanced.

We will all probably agree that our only hope of success in its treatment, rests in a correct diagnosis at the earliest possible moment. It would therefore not be exaggerating the importance of this subject to say that a periodical repetition of the data herein contained may ultimately lead to an earlier recognition of the disease. In the limited time at my disposal I shall dwell only upon its salient clinical characteristics, endeavoring to direct the earnest attention of the general practitioner to the diversification in its symptomatology, and to point out several of the affections with which tabes may be confounded.

The early diagnosis of a disease which, so to speak, is chronic from its very beginning, is of incalculable value, inasmuch as it saves the patient much misdirected and useless medication. When unrecognized tabes has existed for some time, various pronounced symptoms may appear and, although a part of the disease, may conceal its true character. Its presence is frequently unsuspected by the attending physician until the signs are so conspicuous that they almost speak for themselves. The symptoms occurring in the early stage, or at any time during its course, which may lead to its recognition, may be divided into two classes, and are grouped for convenience in the following order:

I. Symptoms Recognized by the Patient.—(*a*) Pains, cutaneous hyperæsthesia, and paræsthesiæ. (*b*) Slowness or difficulty in micturition. (*c*) Diplopia, ocular paralysis, failing or defective vision. (*d*) Transient loss of power in the lower extremities. (*e*) Inco-ordination in walking. (*f*) Visceral symptoms, known as "crises" affecting the gastro-intestinal tract, bladder, or rectum, and occasionally laryngeal crises. (*g*) Disturbance of sexual function.

II. Objective Phenomena Discovered in the Physical Examination.—(*a*) Absence or weakness of the knee jerk. (*b*) Pupillary signs, ocular paralyses, optic atrophy. (*c*) Areas of anæsthesia and retarded conduction of sensation. (*d*) Inco-ordination. (*e*) Insensitiveness to pressure over the ulnar nerves at the elbow in some cases. (*f*) Affections of the bones and joints.

It is not meant to imply that such an array of symptoms is found in every case. That would indeed be very hard lines for the sufferer. It is well, however, to be aware of the probable appearance of one or more of them during the course of the malady. In almost all diseases, as a general rule, relief is sought from the annoyance or discomfort caused by some obtrusive symptom, while many other existing but less troublesome symptoms, although known to the patient, are looked upon by him as trivial or unimportant. Pain, difficulty in walking, bladder trouble, failing vision, or ocular disturbances are the common symptoms that lead the tabetic patient to seek medical advice. The paroxysmal pains, the difficulty in micturition, the rigidity of the pupils, the absence of the knee jerk, and the disturbances of sensibility are the essential elements of the disease and constitute its clinical picture. As tabes is the most common chronic organic disease of the nervous system, the practitioner should always be on the alert for evidence of its presence.

Incontinence or retention of urine is frequently an early symptom. Considerable effort is required in micturition, the urine flowing slowly. Quite often the bladder is not completely emptied and the residual urine may undergo decomposition and thus set up a cystitis. These patients are often treated for a long time for supposed urethral stricture or enlarged prostate, without relief, the surgeon not suspecting the true nature of the trouble.

Pain is often one of the first symptoms in tabes. The character of the tabetic pains is as a rule pathognomonic. They are irregular in their distribution, "sharp," "piercing," "cutting," or "stabbing," being rapidly repeated at the same spot, which often becomes extremely sensitive to the slightest touch. Although they differ essentially from true neuralgic, muscular, or periosteal pains, they are often thoughtlessly considered as being of such origin. Hence it is a common experience of the neurologist to receive such patients with their announcement that they have previously been under treatment for rheumatism or neuralgia. In order fully to appreciate the significance of these pains, it is necessary to study this symptom carefully and minutely. It may surprise some to hear that they are not always confined to the lower extremities. I have records of a number of cases in which the pains were limited to the inframammary, intercostal, dorsal, or lumbar regions. On the other hand in some patients pain is either entirely absent, or only a slight, dull, circumscribed, and aching pain is complained of. In the majority of cases, however, the pain most frequently affects the lower extremities. Indeed, the pains are known to attack almost any part of the body. They may appear in the form of trigeminal facial pain or be located in the scalp.

In some instances the rectum may be the seat of severe pain that is remittent in character. Not being relieved by ordinary means, its true nature being overlooked, surgeons have been led to the fruitless opera-

[1] Read before the New York Medico-Surgical Society, December 6, 1897, and at a meeting of the Passaic County (N. J.) Medical Society, January 18, 1898.

tion of forcibly stretching and paralyzing the anal sphincter and removing any hemorrhoids that perchance are present. At almost any stage suddenly recurring paroxysmal attacks of severe gastralgia may take place, accompanied by exhaustive vomiting, which resists all ordinary methods of treatment but seems to subside spontaneously. Instead of these "gastric crises" there may be severe and unaccountable diarrhœa, associated with violent colicky pain that may sometimes simulate an attack of renal colic. Ignorance of the occurrence of these visceral symptoms is a common source of error in diagnosis.

Sometimes persistent gastralgia may be the only symptom complained of. In such a case careful examination will often reveal an area of cutaneous anæsthesia in the epigastric region, thus leading to further investigation which determines the underlying cause of the pain.

Many tabetics, on account of their various paræsthesiæ and transitory symptoms, have been treated for years as neurasthenics, without their true condition being recognized. This would not occur if the general practitioner was sufficiently familiar with the symptomatology of the disease, and the method of demonstrating its principal objective signs. It is not expected that all general practitioners should be experienced neurologists, but it is a duty they owe to their patients as well as to themselves to avoid such common errors of omission as have just been mentioned.

One of the earliest and most constant objective signs of tabes is the loss of the knee jerk. As a rule it does not disappear suddenly. I can now recall a number of cases in which the pains existed for a long time before the knee jerk disappeared. In the study of a large series of cases the knee-jerk symptom is found to be variable in its character. In quite a number of instances of undoubted tabes I have seen both knee jerks active, but they usually disappear as the disease advances. This occurs when the upper portion of the cord is first affected. In others the knee jerk may be well marked on one side and lost on the other. Again they may be apparently absent, but demonstrable only upon so-called reinforcement. Both may be equally feeble, or differ in degree of weakness. It has been claimed that in about one per cent. of healthy people the knee jerk is absent. The correctness of this assertion is questionable. Such an anomaly is so rare that its possibility need only be remembered. The writer has tested over one thousand healthy children from three to fourteen years of age, and the knee jerk was demonstrable in every case. Its absence is due to an interruption in the so-called reflex arc in relation with the corresponding centre situated in the lumbar region of the cord. Thus it is lost from a pathological process, such as tabes involving the posterior nerve roots or the posterior columns in the lumbar cord, or from a transverse myelitis or poliomyelitis in the same region, or from neuritis or degeneration affecting the anterior crural nerves. It may also be lost in diabetes, in some cases of cerebellar tumor, and in a few other rare lesions. Owing to the absence of the knee jerk, several of the conditions above mentioned are often mistaken for tabes, especially polyneuritis in which the anterior crural nerves are implicated.

On the other hand, I have repeatedly had patients sent to me with the diagnosis of tabes, based upon the alleged absence of the knee jerks, in whom I have had occasion to demonstrate that the knee jerks were not only present but active. Much patience is often required in satisfactorily determining whether the knee jerk is present or absent. The ordinary and customary method of testing for the knee jerk while the person's legs are crossed, or the feet resting on the floor, will suffice when the knee jerks are quite active. Under such circumstances the position of the limbs is immaterial. The utmost care, however, is necessary when there is any doubt as to the presence of the reaction. It will then be advisable to have the patient sit upon a high chair or upon the edge of a table, so that the feet are free from the floor.

As a rule, both sides should be examined. In many instances the anticipation of the tap upon the tendon occasions involuntary rigidity of the flexor group of muscles, thus producing sufficient opposition to overcome the action of the quadriceps. Before and during the examination the patient should close his eyes, and his attention should be directed from the purpose of the examiner, either by conversation or rapid interrogation. Or he may be directed to make some muscular effort with the hands, such as forcibly interlocking the fingers, or elevating the arms, etc. (This is known as "reinforcement.") With this object in view any other similar expedient may be resorted to that suggests itself to the examiner. It is never safe to state that the knee jerk is absent, unless repeated and varied tests have been made with the clothing removed.

Another early and most important evidence of tabes is the loss of the reflex action of the iris to light. This is familiarly known as the Argyll-Robertson symptom. It is present in about eighty per cent. of all cases. Being a phenomenon somewhat analogous to that of the knee jerk, it is found to be just as variable in the extent of its manifestations. Its absence, however, does not exclude the diagnosis of tabes. The longer the duration of the disease, the more likely are we to find this sign. When present it is generally bilateral. In rare instances it is unilateral, *i.e.*, affecting only one eye, or the degree of reaction may differ in the two eyes. It is usually unaccompanied by any disturbance of vision. As a rule, the pupils react in convergence of the optic axes. In some cases of tabes the pupils are absolutely rigid, and do not react to light or in convergence. They may also be unequal, partly dilated, or contracted.

This inaction of the pupil when exposed to light is not indicative of a lesion in the spinal cord, as was erroneously supposed by many before tabes rested upon a firm pathological basis, but is the result of interference with the reflex conducting path in its course between the optic nerve, corpora quadrigemina, and oculo-motorius. It is therefore due to a lesion within the brain, and may be looked upon as an almost infallible sign of central nerve degeneration when the eyes are otherwise apparently normal. This pupillary condition is frequently present in paretic dementia and is not uncommon in cerebral syphilis.

The examination of the pupils for reaction to light requires the closest observance in its performance. This apparently simple procedure is deserving of careful attention, and certain precautions are absolutely essential in order to avoid erroneous conclusions.

The following method should be pursued: Place the patient in a position facing a window. Daylight is always preferable. Instruct him to gaze steadily upon some large object, at least twenty feet distant, and to keep both eyes open. The eyes are then covered or shaded either with the examiner's hands or with two pieces of dark card board. The patient in the mean time must continue gazing in the direction just mentioned. In a few moments one eye is suddenly uncovered and exposed to the light, when in the normal state the pupil (which always dilates in darkness or subdued light) immediately contracts. The other eye is then tested in the same manner.

The next step is to note if the pupils contract in convergence or accommodation. After the patient has been looking in the distance for a short time, with both eyes uncovered, he is suddenly told to look at

the examiner's finger, or some small object held within two inches of the patient's nose. In the normal condition the eyes converge and the pupils contract. The pupillary reactions should not be tested before a gas flame, as the patient is apt to and, in fact, generally does "fix" upon the flame, thereby causing contraction of the pupils in accommodation and convergence, which may easily mislead. A very common source of error to be guarded against, which is similar in its result, is the failure to bear in mind the natural tendency of the patient to look at the examiner as soon as the eye is uncovered.

I have thus entered into a detailed description of the method of eliciting these two objective symptoms on account of their paramount importance. Incorrect conclusions are too often based upon apparent demonstration of physical signs that do not exist in reality.

Another objective symptom of considerable corroborative value is the circumscribed areas of cutaneous anæsthesia which are often found distributed over the trunk, particularly over the thorax and back.

Paralysis of an eye muscle, which may be either transient or permanent, or primary optic atrophy with failing vision, are among the early manifestations of tabes. This leads the patient to consult the ophthalmologist, who is justly suspicious of the presence of tabes in the latter condition, while the former is often incorrectly attributed to cerebral syphilis. In a large proportion of cases the disease is first discovered through this channel. The transitory character of an ocular paralysis should lead us to suspect the presence of tabes. On the other hand such patients may have central vision preserved for a long time, and yet optic atrophy may be well advanced. It is therefore advisable to examine the visual field in all cases of suspected tabes. When atrophy is present, the field for form will often be found irregularly contracted—sometimes to a remarkable extent—without any interference with the patient's comfort.

Sexual impotence, or the painless enlargement and disorganization of a joint, is occasionally the first obtrusive symptom that prompts the patient to seek medical advice.

The popular designation of this disease as "locomotor ataxia" is objectionable, although the common use of this name seems to be sanctioned by a custom which is rapidly losing ground. The term "locomotor ataxia" is virtually descriptive of a symptom which in itself is not characteristic of the affection. It is gradually being replaced by the term "tabes." The symptom of ataxia in locomotion or in standing may either be entirely absent or may not appear until late in the course of the disease. It is present, however, in greater or lesser degree in a large proportion of cases, but is rarely an early manifestation. On the other hand, an erroneous diagnosis of tabes has often been made from the presence of ataxia in standing. To tell a patient to put his feet together and stand with closed eyes is a simple matter. Should he sway from side to side or fall, we call this static ataxia. Although it frequently occurs in tabes, it is by no means pathognomonic. The fact that a slight swaying is of common occurrence in healthy individuals should always be borne in mind.

Static inco-ordination is often present in hysteria or pronounced neurasthenia, during convalescence after prolonged illness, in transverse myelitis, and in polyneuritis resulting from diphtheria, alcohol, lead, arsenic, etc.

Some forms of alcoholic polyneuritis are commonly mistaken for tabes on account of their resemblance to that affection. Upon superficial examination the presence of static ataxia with anæsthesia and absence of the knee jerk, all point to tabes. But as these symptoms are usually associated with tenderness on pressure over the affected nerve trunks, diminished muscular power or actual paralysis and decrease or loss of faradic irritability in the affected muscles, we are enabled to exclude tabes. The absence of the knee jerk in these cases is due to involvement of the motor fibres of the anterior crural nerve or its branches, and is usually an accompaniment of weakness or diminished resistance in the quadriceps. The loss of the knee jerk in uncomplicated cases of tabes, however, is attended as a rule with preservation of muscular power in the extensor group, even when the disease is well advanced and there is pronounced inco-ordination. This peculiar feature of tabes can be easily demonstrated, and in my experience is of extreme value.

When the peripheral sensory nerves are especially affected, as in certain forms of toxic polyneuritis, particularly from arsenical poisoning, the disease has been termed pseudo-tabes. On account of the presence of well-marked ataxia, absence of the knee jerks, and anæsthesia, it closely resembles the true disease. A consideration of the antecedent history, mode of onset, and development will generally enable us to reach a satisfactory conclusion as to the nature of the trouble.

At times the differential diagnosis between tabes and some atypical forms of polyneuritis is attended with much difficulty. On the other hand, in some tabetic patients the peripheral nerves of the lower extremities may undergo degeneration, and thus lend confusion to the otherwise stereotyped picture. I have repeatedly seen transverse dorsal myelitis mistaken for tabes, owing to pain in the lower extremities, inability to stand with closed eyes, and cutaneous anæsthesia. Such an error must be ascribed to gross carelessness or neglect in the examination. The exaggerated knee jerks with probable ankle clonus, and the loss of muscular power sometimes with atrophy, should serve to make the diagnosis clear. Some cases of cerebro-spinal syphilis so closely simulate genuine tabes that their differentiation can be accomplished only after a careful study of the development and course of the symptoms. Paretic dementia and tabes are sometimes found associated, but when the mental symptoms predominate, such as changes in the patient's character, diminution of the intellectual functions, speech disturbances, attacks of unconsciousness, etc., we must favor the diagnosis of the former.

It will thus be seen that the most important subjective symptom is the peculiar paroxysmal pains, while the two principal objective signs of tabes are the absence of the knee jerk and the loss of the pupillary light reflex. It may be safely said that the coexistence of the latter is equivalent to the diagnosis of tabes. It rarely happens that both are absent at the same time, yet such cases do occasionally occur. We must then depend upon the association of other symptoms and watch for further developments. The presence of either one, in conjunction with the fulgurating pains, or bladder disturbance, or the areas of anæsthesia over the back, is sufficient evidence to warrant the diagnosis. When a man, over thirty years of age, with a history of ancient syphilitic infection, complains of the pains characteristic of tabes, we should at once suspect its existence, whether other signs are present or not. Should these typical pains be associated with one or more of the objective symptoms, the diagnosis may be made with confidence.

It is a fact well known to all neurologists that among physicians in general the failure to recognize the presence of tabes is more common than its diagnosis. On the other hand, an incorrect interpretation of phenomena which resemble those of tabes is of frequent occurrence. Such conditions can be obviated only, first, by a clear conception of the clinical peculiarities of the disease; second, by a practical famil-

iarity with the method of examination, combined with its application to the individual case.

In such a brief paper the writer has necessarily refrained from the introduction of illustrative histories, and has attempted only to outline the most important diagnostic features of the disease.

THE RELATION OF SOME FORMS OF CONSTIPATION TO DEGENERACY.

BY EDWARD H. WILLIAMS, M.D.,

MANHATTAN STATE HOSPITAL, NEW YORK CITY.

STIGMATA of degeneration are seen so frequently upon so many organs of the human anatomy that there is justification of the supposition that almost every organ may be sometimes affected. Such stigmata upon the ear, palate, or jaw are so conspicuous and so easily examined that they have naturally attracted closer attention than those affecting the internal organs; but there is reason to believe that the alimentary tract comes in for its share of these marks of degeneracy. There is no good physiological reason why the ear, for example, should be selected by nature rather than the liver, as the organ upon which to stamp her mark of degeneracy; and, while at present there may be little positive evidence that such stigmata are often found in the liver, there is certainly little evidence that would negative such a supposition.

The study of the known stigmata is so comparatively new that the subject has not yet been threshed over and over, as has almost every disorder of the internal organs. The result is that there is a tendency to account for a malformed palate with the single word "degeneracy," while some obscure disorder of the alimentary tract, which may be just as much an effect of degeneration, is christened as an "itis," so many forms of which have been handed down for generations in medical literature. For it is much easier to adapt almost every obscure disease to one of the multitudinous "isms" or to call it an "itis," than to trace through obscure ancestral lines and intricate paternal and maternal anatomical anomalies in search of proof of degeneracy, with little prospect of sufficient requital in the end.

The condition of chronic constipation so frequently found existing among classes of well-recognized degenerates seems sometimes to be a congenital defect; but this condition is seen also in cases that are apparently free from the marks of degeneration. In such obscure cases, however, a careful examination will sometimes reveal other conditions which point to degeneracy. In institutions for the treatment of abnormal mental conditions—that is, for insanity, idiocy, and epilepsy—chronic constipation is a universal complaint, and cathartics and laxatives play an important part in the medical treatment given in such institutions. And while large numbers of the inmates of these institutions show characteristic maxillary, palatal, or other recognized stigmata of degeneracy, there is usually no organic disease detectable in the organs of the alimentary tract. As far as can be ascertained, the liver, pancreas, spleen, kidneys, and all the intestinal glands are, organically at least, in a normal condition. Of course functionally some of them must be abnormal, and between this condition and mental abnormality there is apparently some connection, since they so frequently exist together.

Occasionally, however, cases are seen in which there are no mental abnormality and no conspicuous stigmata of degeneration, but in which a chronic constipation has existed from childhood and which cannot be accounted for except as a congenital defect. If a thorough examination is made in such cases it is often surprising to find how many stigmata do really exist, and how narrow an escape from degeneracy some most intelligent and "well-balanced" people have had. A careful examination of ancestral records, when they exist, often throws a new light upon an otherwise obscure picture, as in the following cases of two brothers. These two brothers were men of exceptional intelligence, and also of unusual size and muscular development. Instinctively of a scholarly bent, they were also athletes as well, and apparently as nearly normal men, mentally and physically, as are found in any walk of life. But both of them were troubled with a tendency to constipation which had existed since their earliest recollection. Even when in the pink of condition as college athletes this tendency still asserted itself, necessitating the constant use of mild laxatives. It was this anomalous condition which led to a careful examination for stigmata of degeneration and a search of the ancestral records. In both brothers I found a slight but significant anomaly in the upper maxilla. The older brother had a supernumerary tooth in the upper jaw, there being two instead of one lateral incisor on the left side; but the tooth alignment was so perfect that even intelligent dentists had failed to notice the extra incisor. The central incisors were perhaps an eighth of an inch to the right of the median line, but straight, and the entire arch and all of the teeth were beautifully formed. In the upper jaw of the younger brother I found that the first bicuspid on either side was absent. It was apparently from defective dentition, there being no spaces for them, the hard palate showing corresponding constriction. The alignment, however, was almost perfect.

On examining the ancestral records, which fortunately were unusually complete, some significant data were found. The father had been a professional man who came from a long line of cultured professional men. He was a man of considerable ability, but lacking in the push and stamina which characterize men of a vigorous race. In stature he was rather above the average, but he was of poor muscular development. He was apparently one of those men so frequently seen in aristocratic lineages, who, while not degenerates themselves, are close to the border line, and whose children are likely to be degenerate unless intermarriage with some vigorous and less ancient line acts as an extenuating factor. In this instance the marriage had been a most fortunate one. His wife, a highly intelligent and unusually vigorous woman, came from a race of hardy Scotch Highlanders, who, three generations before, had immigrated into one of the frontier territories of America and there produced a race as vigorous as the original stock. With few exceptions the members of this family had been of unusual muscular development and energy. From this union of degenerate aristocracy and vigorous Highland stock came the two brothers, partaking of the refined tastes of the paternal branch, and having combined with it the athletic vigor of the maternal branch. In going over the ancestral records of both branches of the family, I found that the father's mother (who, like her husband, was descended from a long line of highly cultured ancestry) had a peculiarity in jaw formation. The upper jaw was much constricted, with absence of several teeth and marked irregularity of the others. The lower jaw was either actually protrusive, or apparently so from the undeveloped condition of the upper. Her mother had had a supernumerary incisor tooth almost identical with the condition spoken of in the tooth formation of the older brother, except that the upper jaw was not fully developed, the alignment of the teeth being imperfect on account of this constriction.

The chronic constipation so persistent in both

brothers seemed to be due largely to a lack of "tone" in the alimentary tract; and by careful observation a peculiarity of the muscular systems was discovered which might be regarded as akin to the intestinal inertia. By careful comparison with other athletes, both in and out of training, it was found that the muscular systems of both brothers tended to lose "tone" when not in training very much more rapidly than is customary with ordinary athletes. They were able to get into "condition" in an unusually short time, and when trained showed unusually strong and active muscular systems; but the muscular "tone" left them rapidly when not in training. This apparently paradoxical condition of the muscular system was perhaps due to the inherited disposition of both paternal and maternal ancestry, the characteristics of the muscular Highland stock predominating during activity, and the more æsthetic lineage being represented at other times.

In this connection it should not be forgotten that victims of inebriety often give a history of chronic constipation which existed long before they became addicted to the use of alcohol; and there is almost invariably a neurotic taint in the direct ancestry of such cases. And it is often found that the progeny of such inebriates have a tendency to constipation, even when not having a strong tendency to inebriety. The inference which may be drawn from such cases is that there is some congenital defect, which may perhaps be a manifestation of the same force that produces a Morel ear or a deformed palate, but is exerted on the muscular and glandular systems instead of the osseous or fibrous structures.

A NEW, RAPID, AND ACCURATE METHOD OF ESTIMATING URIC ACID.

By R. HARVEY COOK, A.M., M.D.,

ASSISTANT PHYSICIAN, OXFORD RETREAT, OXFORD, OHIO.

MANY patients with nervous disorder, varying from the mildest neurasthenia to the most marked cases of melancholia, are brought to our sanatorium each year, who could have been successfully treated at home had the physician examined for a plus excretion of uric acid The belief that the failure to make such an examination was due, not to neglect, but rather to an inability on the part of the attending physician, has led me to give my method of estimating the amount of uric acid.

All previous methods with which I am familiar not only consume time but require a thorough knowledge of chemistry. In my experience with physicians, however competent they may be in chemical work, but few are provided with the apparatus and solutions required in quantitative analyses. All former quantitative estimations of uric acid with which I am acquainted have been made either by a process of weighing or by a trituration method. If uric acid is estimated by Salkowski's method, the following objections can be found: first, several hours are consumed in making the test; second, a very delicate scale is necessary in order to obtain an accurate estimation. Such a scale is not only of but very little use to the physician, but is an expensive item.

Several titration tests are advised. The most generally used is probably Haycraft's. The greatest objection to this test is that it is not accurate. The percentage of urate of silver is apt to be lost in the filtering and washing process. Again, a discrepancy is often due to having a solution of ammonic thiocyanate which is not standard; moreover, this test necessitates a technique essential in all quantitative analyses. Another objection to the Haycraft test is that, in order to do the work in anything like a satisfactory manner, a water pressure is required to operate the vacuum pump; this alone renders the test practically useless to the majority of physicians in the smaller towns. Several other titration tests are advised by chemists as being accurate in the estimation of uric acid, but the time required, the essential technique, and the apparatus necessary render all previous tests impracticable to physicians.

My method is chemically the same as Haycraft's, in that the uric acid is thrown down as urate of silver. The method which I propose is rapid, accurate, and easily carried out. The following apparatus is necessary: a centrifugal machine, four graduated tubes of a capacity of fifteen cubic centimetres each, and a pipette holding one cubic centimetre. Assuming that the majority of physicians have a centrifugal machine for the examination of blood, sputum, and urinary sediment, the only additional apparatus needed is the graduated tubes. These tubes must be fifteen cubic centimetres in capacity, but need be graduated only to ten cubic centimetres, the essential feature being an accurate graduation.

Method of Procedure.—Place in the graduated tubes 10 c.c. of urine; add to this from 0.5 to 1 gram of sodium carbonate and from 1 to 2 c.c. of ammonium hydrate. Shake until the sodium carbonate is dissolved; this precipitates the earthy phosphates. Separate this precipitate with the centrifugal machine and decant the supernatant urine into another graduated tube. It will be found that the earthy phosphates are readily separated and adhere to the bottom of the tube; this allows the clear urine to be readily poured off into another tube. To the clear urine now free from phosphates add 2 c.c. of ammonium hydrate and 2 c.c. of ammonic silver solution (made by dissolving 5 gm. of silver nitrate in 100 c.c. of water and adding ammonia until the solution becomes clear). The addition of the silver solution causes the uric acid to be precipitated as the urate of silver, a translucent slimy substance. Separate this precipitate with the centrifugal machine and pour off the supernatant urine. Add to the precipitate an excess of ammonium hydrate, at least 5 c.c., and mix thoroughly. By this last step any of the chlorides that may have been precipitated are redissolved, leaving only a pure urate of silver. Lastly, precipitate this urate of silver until the lowest reading is to be had.

Each 1 c.c. as marked on the graduated tube indicates 0.001176 gm. of uric acid in 10 c.c. of urine. For example: if 0.5 c.c. be the lowest reading, you then have $5 \times 0.001176 = 0.00588$ gm. of uric acid in 10 c.c. of urine. In order to obtain the percentage, multiply this result by 10. If the number of cubic centimetres of urine passed in twenty-four hours is known, the total uric acid can be easily calculated. It will be found advantageous to carry two specimens through the examination at the same time; thereby the centrifugal machine is equally balanced.

For the causes influencing the excretion of uric acid and its relation to urea, as well as the clinical manifestation of an excess of uric acid in the system, I refer the reader to Haig's work on "Uric Acid in the Causation of Disease."

Flatfoot.—I believe that pronation, with or without flattening of the arch, is the factor to study, and that its prevention and its cure are the prevention and cure not only of flatfoot, but of the painful affection without breaking down of the arch which I speak of as pronated foot: that the selection and use of proper boots will cut down very much the use and need of mechanical appliances.—LOVETT, *Canada Lancet.*

THE MEANING OF THE WORD PHOSPHATURIA.

BY GEORGE FREDERICK LAIDLAW, M.D.,

NEW YORK.

IN Foster's Medical Dictionary (New York, 1894), phosphaturia is defined as "a state in which an excessive amount of phosphates is excreted in the urine." In the "Twentieth Century Practice of Medicine" (New York, 1895), Fenwick defines phosphaturia as a "symptom" consisting of "the persistent and excessive elimination of alkaline and earthy phosphates in sterile urine."

It needs but a cursory glance over recent medical literature, however, to learn that the term phosphaturia is frequently employed to indicate an entirely different condition, namely, the ready precipitation of the earthy phosphates from the urine, either spontaneously or on the application of heat; or, on the other hand, a high percentage of phosphates in a given specimen. It is in this latter sense that the word is used in such recent and authoritative works as Loomis and Thompson's "Practice of Medicine" (New York, 1897), Wood and Fitz's "Practice of Medicine" (Philadelphia, 1897), Anders' "Practice of Medicine" (Philadelphia, 1897), Hare's "System of Therapeutics" (Philadelphia, 1892), Purdy's "Practical Urinalysis" (New York, 1895), Tyson's "Guide to the Practical Examination of Urine" (Philadelphia, 1886), and others too numerous to catalogue. It is true that most of these writers warn the reader that a quantitative analysis of the total phosphates excreted in twenty-four hours is necessary for the diagnosis of phosphaturia; but in the next line they themselves offend by confusing phosphatic precipitation with excessive elimination, shifting aimlessly from the one to the other and rehearsing diagnostic tests that are not only worthless but are also misleading. I defy any physician to gather from these articles on phosphaturia any reliable method of diagnosis and differentiation. Verily, it would have been better for these authors to have followed the example of Tyson in his recent "Practice of Medicine" (Philadelphia, 1896) and ignore the subject as a thing that has never been. Fortunately the disease is neither common nor fatal.

The cause of all this confusion seems to be the lack of some word to express that state of the urine in which it easily precipitates its earthy phosphates. In the absence of such a word authors have taken the word phosphaturia, to which a totally different meaning has been given by the authorities (Foster's and other medical dictionaries). In this "attempt to put new wine into old bottles," the articles on phosphaturia in our best text-books are hopelessly muddled.

Let it be understood that in the urine there are phosphates and phosphates; there is the easily soluble sodium phosphate, forming about two-thirds of the entire amount, and there are the two less soluble earthy phosphates, forming the remaining third. In urine of acid reaction these salts are held in solution. Either boiling or putrefaction diminishes the acidity of the urine and the slightly soluble earthy phosphates are apt to be thrown down, but one cannot judge the total excretion of phosphates by the amount of this sediment, because a much larger and uncertain quantity of sodium phosphate remains in solution, unmeasured and unknown. Nor can one learn anything of the phosphatic excretion by precipitating all of the phosphates with magnesian fluid and estimating their abundance by the height of the column in a test tube, as in the method of Vogel. This absolutely worthless procedure has been copied from one text-book to another without criticism (Tyson, Purdy, Hoffmann and Ultzmann, and others). To appreciate this error, one has but to reflect upon the urine of acute nephritis, which often shows a large percentage of urea (ten, fourteen, or even eighteen grains to the ounce), whereas, owing to the small quantity of urine passed in a given time, the total excretion is far below the normal; and, in like manner, one who interprets a large percentage of phosphates as an absolute increase, or *vice versa*, will remain in profound ignorance of the true state of the urine. Precipitation from a sample of the accumulated urine of twenty-four hours, as recommended by Tessier, gives a fair basis for calculation of the total phosphates, but this procedure does not give so accurate results as the equally simple quantitative analysis of the phosphoric acid by titration with uranium nitrate.

In his article on phosphaturia in the "Twentieth Century Practice of Medicine," Fenwick grapples with this question, and here at last we find a sharp distinction drawn between, first, a true phosphaturia, *i.e.*, an actual increase in phosphatic elimination as determined by chemical analysis, and, secondly, that condition in which the urine easily deposits its less soluble phosphates. On one page Fenwick calls this latter condition "functional phosphaturia" and on the next page "transient phosphatic urine;" but it seems to me that neither term is well chosen, for the following reasons: The words "transient phosphatic urine" mean nothing; for all urine is phosphatic. The word "transient" is inapplicable, because the condition is sometimes persistent. "Functional phosphaturia" is still more objectionable. The word "functional" is misleading because it implies a phosphaturia unconnected with organic lesion as distinguished from an organic phosphaturia; but "true phosphaturia" has never been associated with an organic lesion and, for all we know to the contrary, may be functional too. Moreover, by the terms of Fenwick's own definition, this "transient" or "functional" phosphatic deposit has no right to the name phosphaturia; for it does not involve any increase in the elimination of phosphates. Again, as in Dickinson's cases, the two conditions of excess and precipitation sometimes coincide; in which case, by Fenwick's nomenclature, we should have a phosphaturia at once "true" and "functional" or "transient" and persistent—a manifest absurdity.

To facilitate accuracy and precision in this chaotic literature of the urinary phosphates, I would propose the use of the word "phosphaturoptosis," indicating simply the precipitation of the phosphates from the urine. Though of somewhat Teutonic proportions, I prefer to regard this word as possessing Hellenic grace and fitness. It has the advantage of meaning just what it indicates and nothing more, leaving such compromising adjectives as functional, transient, neurotic, or other designations of unknown characteristics for future study and verification.

That this condition of phosphaturoptosis is of no importance I do not admit; for from such urines calculi of calcium phosphate are sometimes deposited, and I maintain that phosphatic calculus, or any other calculus, is a matter of much importance, and that the urinary condition that favors it, though not a "true phosphaturia," is at least worthy of a name and a place in medical records.

In the only case of true phosphaturia that has come under my notice, out of a series of nearly two thousand urinalyses for all causes, the urine was strongly acid in reaction and the earthy phosphates were held well in solution; but cases are recorded in which both phosphaturia and phosphaturoptosis were present.

Fenwick's classification of the fermenting alkaline urines of cystitis, with their accompanying phosphatic deposits as "secondary phosphaturia," seems to me a good one but for the repetition of that unlucky word "phosphaturia." Here, again, there is no increase

in phosphatic elimination but only a precipitation, a phosphaturoptosis. A secondary or putrefactive phosphaturoptosis is readily distinguished from a primary phosphaturoptosis, in which the urine deposits its phosphates while freshly formed; and by the use of this word both conditions are separated distinctly from phosphaturia, thus embodying in our terminology the distinctions that we must make in practice.

Clinical Department.

DILUTE SULPHURIC ACID IN SURGICAL DRESSINGS.

By H. C. MANSFIELD, D.D.S.,

JEFFERSON, WIS.

In stepping from a passenger train, moving at the rate of twenty-five miles an hour, recently, being out of practice somewhat, I was thrown violently forward. The ground was of the nature of hard-packed sand, and I could not help sliding about my length on hands and knees. When I finally stopped, the concussion on the ball of one thumb and the grinding of the back of the left hand along the space mentioned caused some pain and the parts instantly began to swell. I bathed the parts with a solution of permanganate of potassium and then washed them with dilute sulphuric acid, which was all I had on hand at the time, to make sure of having the surface aseptic. What was my surprise next morning to find a firm leathery scab over all the wounds, and it seemed very grateful, especially on the palm of the hand and ball of the thumb, where the wound was as large as one's fingernail in size. The swelling gradually subsided the next day. No other dressing was required and everything healed nicely in a few days, leaving, however, a sort of a drawn eschar on both hands. The point I wish to make is in regard to the value of dilute sulphuric-acid dressing as being simple and fully equal to and possessing advantages over iodoform and the newer remedies that are said to be taking its place. It is also quite as safe and convenient to use. This may prove of value to some one when the more costly remedies cannot be had.

PYÆMIA IN A BOY THIRTEEN YEARS OLD.

By HERMAN B. SHEFFIELD, M.D.,

INSTRUCTOR IN SURGERY AT THE NEW YORK SCHOOL OF CLINICAL MEDICINE; PHYSICIAN TO THE HEBREW SHELTERING GUARDIAN SOCIETY ORPHAN ASYLUM.

The boy in question was an inmate of the asylum for over six years, always having enjoyed perfect health. His father and mother are living and in good health. On September 3, 1897, he presented himself at the infirmary, with a small pustule in front of the ankle-joint, which resulted, he thought, from pressure of the shoe. The pustule was incised and dressed with iodoform gauze, after evacuation of the pus. The following day he was admitted to the hospital, with a chill and headache. The latter improved after the administration of two and one-half grains of calomel. The pustule had almost entirely healed.

September 6th, chill at 10 A.M., followed by profuse sweating. Faint pericardial friction sound, heard loudest over the base of the heart. Complained occasionally of severe frontal headache.

September 7th, former symptoms increased; delirium; pericardial murmur louder and more diffuse.

September 8th, symptoms of collapse at 12 M.; profuse sweating. Nausea at 6 P.M. Pleuritic friction sound along left axillary line at junction of sixth to eighth ribs. The patient complained of severe stitch pain in this side. Short, hacking cough. Precordial region greatly enlarged and prominent; flat on percussion. Appearance of small vesicles, resembling those of varicella, along legs and soles of feet.

September 9th, all symptoms more severe in character. Pain in left groin. Urine loaded with albumin, pus and blood cells, hyaline and epithelial casts. Troublesome cough and dyspnœa. Feet icy cold. Body hot and bathed in profuse perspiration. Crepitation over several spots of the chest.

September 10th, stiffness of limbs; marked delirium; bronchial breathing instead of the previous crepitation; enlargement of the spleen and liver.

September 11th, partial paralysis of entire right side of the body. Speech thick, difficult, and incoherent. Slight perspiration. Unconscious most of the time. Pericardial sounds markedly fainter.

September 12th, 13th, 14th, general condition seemingly a little improved.

During the whole illness the patient took plenty of nourishment and never vomited. Paralysis of the sphincter ani was manifest on the 11th. The temperature varied from 105° to 107° F., and was not intermittent in character. This would seem to be opposed to the teachings of most text-books. The pulse corresponded with the rise and fall of the temperature; it averaged 130 a minute, and presented nothing peculiar. The respiration changed with the development of the complications. It averaged 50 per minute. On September 9th it stood above 70 for over six hours.

Examination of the blood, undertaken three times during the ten days of illness, showed nothing abnormal except an increase in the number of white blood corpuscles, and on one occasion two diplococci were found lying in or upon a red blood corpuscle.

September 15th, the patient developed pulmonary œdema and died.

Post-mortem examination six hours after death: Body well nourished. Signs of decomposition on the face and chest. No rigor mortis. Precordium very prominent. A small incision made in this location gave exit to about one and one-half pints of purulent, fibrino-sanguinolent fluid. The heart was enlarged and darker than normal. The pulmonary valve was perforated, and upon the edges were seen yellowish-white vegetations. Vegetations were also present below the aortic valve and upon the endocardium. There was a purulent exudation upon the surface of the pericardium, which was firmly adherent to some portions. Pericardium adherent to the pleura. The liver was congested and greatly enlarged; very small pustules covered the surface, and purulent foci were found along the portal branches. The spleen was much enlarged, blackish-red in color, mushy, and almost liquid. Kidney.—A large number of small abscesses, the size varying from one to two pinheads, were found scattered chiefly in the cortex. They were yellowish-white in the centre, surrounded by a distinct, bright red area. The organ was enlarged and more flabby in consistence than normal; the markings were obscured. The capsule was partly adherent, and when it was separated from the underlying tissues minute drops of pus were seen to exude at the points where the abscesses were located. Lungs and pleura.—There was a very extensive exudation over the pleura, which adhered to the surface of the lungs. On section, numerous wedge-shaped foci of consolidation, deep red in color, were found scattered throughout the lung substance, principally near the pleural surface. The bases of these foci were directed toward the pleural surface. The brain could not be obtained; but, judging from the partial hemiplegia, the presence of diseased foci could justly be surmised.

Cultures and microscopic slides were taken from the vegetations upon the heart valves and from the kidney

abscesses. In both cases the staphylococcus pyogenes aureus and streptococcus pyogenes were found. The latter bacterium was predominant in the cultures obtained from the heart vegetations.

The etiology of the case in question could be traced only to the small and apparently insignificant abrasion at the ankle-joint; for the patient was otherwise in excellent condition. It is difficult to understand why so many larger, dirty wounds in patients with broken-down constitutions escape infection, while this trifling injury proved to be the source of death to the robust boy: moreover, as the wound was entirely healed at the beginning of the disease, the temperature was certainly extraordinarily high.

Another peculiar feature of this case was the absence of any signs of derangement of the cardiac valves, notwithstanding the marked lesions found there at the necropsy.

The observation that this case was a result of streptococcus and staphylococcus infection fortifies the recently advanced opinion that the antitoxins of these micro-organisms ought immediately to be employed in pyæmia with obscure etiology. The fatality of this disease under other methods of treatment, and the encouraging results obtained from the administration of the antitoxins, certainly speak favorably of the latter. At all events, the latter method of treatment is certainly to be recommended.

One Hundred and Fiftieth Street and Eleventh Avenue.

A METHOD TO DETERMINE THE PRESENCE OF SMALL EFFUSIONS INTO THE KNEE-JOINT.

By JAMES PORTER FISKE, M.D.,

NEW YORK,

INSTRUCTOR IN ORTHOPÆDIC SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSISTANT SURGEON, ROOSEVELT HOSPITAL, O.-P. D.

The patient assumes the standing posture, the knee-joints being fully extended. The patient then bends forward at the hip-joints, resting both hands on the anterior surface of each thigh about the mid-third, extreme extension at the knee-joints being maintained. This is really a position of ease for the patient, and by this position of examination we have the structures posterior to the knee-joint rendered tense, while the structures anterior, including the capsule, are relaxed. The patient, bending forward at the hip-joint and pressing downward with the hands on each rectus femoris, relaxes this muscle to a marked degree. Any fluid which may be present sinks at once and settles behind the patella; that is, by this method we obtain the benefit of gravity. The examiner, standing beside the patient, locates accurately the centre of the patella and gives it a smart tap. If fluid be present, we obtain the patella tap.

The position of the patient, *i.e.*, one of ease and anterior relaxation, combined with gravity, are the features of this test. The muscular spasm or anterior rigidity, often present during the ordinary examination of a knee-joint, is absent. In striking the patella the pressure must be applied at its centre and directed toward the femur. If either extremity of the patella be struck, we obtain a tilting which is deceptive; also we must guard against a lateral sliding, very easily obtained in this position of extreme anterior relaxation. No manipulation of the joint is necessary, and, in fact, should be avoided in making this test.

Many cases which have been considered doubtful as regards the presence of fluid have by this method of examination been correctly diagnosed. A slight injury to the structures about the joint without an accompanying synovial effusion might very well be treated by local application and massage, while the presence of a very small joint effusion indicating an accompanying synovitis might if appreciated cause the surgeon to employ other methods of treatment—such as absolute fixation, counter-irritation, or compression. Again, in a knee-joint which has been the seat of an acute serous synovitis and where the effusion has almost subsided, the subsequent treatment as regards protection or use might very well depend on the presence or absence of fluid. In such cases this test is of value, as it demonstrates even a very small effusion.

In the examination of many joints where the amount of fluid present was slight, I have found this an accurate and delicate test.

Progress of Medical Science.

Pericardotomy and its Anatomical Basis.—Dr. A. Worintsch-Sjanoschenski (*Annals of Russian Surgery*, 1897, Bk. 3-5) has come to the following conclusions: Normally the anterior intrapleural space varies considerably; to the left of the sternum its boundaries are more fixed than to the right. In studying this question upon the cadaver, the operator must be very careful, since many pathological processes change the boundaries of the intrapleural space. In pericarditis with effusion, an exploratory puncture gives valuable information; it is only as the result of such exploratory puncture that the operative procedure can be decided upon—aspiration or pericardotomy.

Enchondroma of the Cervical Vertebræ.—Dr. O. Föderl (*Deutsche Zeitschrift für Chirurgie*, Bd. xlv., p. 154) describes the above extremely rare condition, occurring in a thirty-five-year-old woman. For three years her neck had gradually grown larger, attended with anterior displacement of the larynx and trachea. The patient came under observation suffering from severe dyspnœa, which necessitated a tracheotomy. She died two days after operation. The autopsy revealed a large enchondroma, hyaline in structure, originating from the seventh cervical vertebra; in places the tumor showed mucoid and calcareous degeneration.

Acute Pleurisy.—The vocal resonance is usually diminished or absent. The whispered voice is said to be transmitted through a serous but not through a purulent exudate (Baccelli's sign). There may, however, be intensification bronchophony. The voice sometimes has a curious nasal squeaking character, which was termed by Laennec ægophony, from its supposed resemblance to the bleating of a goat. In typical form this is not common, but it is by no means rare to hear a curious twang-like quality in the voice, particularly at the outer angle of the scapula.—William Osler, "Principles and Practice of Medicine," page 562.

The Tetanus-Antitoxin Properties of the Normal Central Nervous System.—A. Wassermann, of Berlin, and T. Takaki, of Japan, claim to have proven by means of experiment that the normal brain and spinal cord possess an antitoxic effect against tetanus, whereas no other organ has this peculiarity. The tetanus-antitoxic effect of the brains of normal guinea-pig is such that one centimetre of brain emulsion neutralizes ten times the fatal dose of the tetanus poison. The antitoxic effect of the spinal cord is weaker than that of the brain, inasmuch as one centimetre of its emulsion neutralizes but three times the fatal dose of tetanus. The authors believe that the antitoxic power of the brain and cord is to be traced to an inherent peculiarity of the cells.—*Wiener klinische Rundschau*, January, 1898.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 12, 1898.

THE PROPOSED DEPARTMENT OF PUBLIC HEALTH AND ITS LEGISLATIVE ASPECTS.

ON a former occasion, in calling attention to the obvious necessities for a national system of quarantine, we strenuously urged the amplification of the present Marine Hospital system as the most desirable and practical means to such an end. We are quite well convinced that the more thoroughly this great question is studied in its broadest signification the more readily can it be seen that there is but one conclusion to be arrived at. The opposition to the Marine Hospital bill by the advocates of the Spooner bill, if effective at all, will result in no compromise whatsoever, and the fundamental questions involved will be as far from a final settlement as ever. In other words, unless we can get the Caffery bill passed, no other measure will be seriously entertained by Congress. The legislators are inclined quite properly to view the matter in the very practical light of the end justifying the means.

Among the first questions that would be asked by the average legislator before whom such a proposition was placed would be: "What interests require this enactment, and what are the reasons for it?" The legislator seeking information on these points would naturally be guided in his judgment by the character of the persons seeking to engraft such an addition upon our governmental system; and rightly, too, because, however much the plan might have theoretical merits, yet there are many things which are good in the abstract which are not practical in their application or timely in their consideration. If the legislator should ascertain, after a public hearing, that but three gentlemen appeared in behalf of such a bill, and that those three gentlemen were local officials who would be personally benefited by its enactment, he would be justified in coming to the conclusion that whatever sentiment had been drummed up in its favor was tinged by immediate self-interest or prospective personal advancement.

As a practical legislator, his next question as a conservator of the public interests would be: "What will such a department or commission cost annually to the taxpayers?" This question at this particular time is more likely to be asked than at any other, because this is a time when the finances of the government must be carefully nursed, and every attention paid to the economical administration of affairs. This is not a time when the public revenues are so ample that a department of public health with forty-five new and indefinitely expensive officials can be viewed with other than serious concern by a careful and conservative servant of the public, who has the expenditure of the country's money given to him as a trust by the people.

These considerations appeal to us as they have appealed to members of Congress when they have taken under advisement the proposition to establish a commission or department of public health, as proposed by the Spooner bill. No one of the gentlemen active in that propaganda has offered an opinion as to the ultimate cost of this project. It is a scheme so immature that even its promotors have not yet settled to a definite conclusion what they want or how much they want; and at the public hearing before the house committee on interstate and foreign commerce, the chairman of the subcommittee, Dr. U. O. B. Wingate, who drew it up, gravely announced that sections 14 and 22 of the bill, which give it its national character, would probably be withdrawn. It has undergone so many modifications that this latest move on the part of the committee leads one to suspect that any modification would be accepted, provided it could get Congress to indorse its position. No one seriously attacks the proposition to secure national supervision of health matters, in some form or other. It is not only largely a question of form, but also of means and the practical features involved in obtaining them. A good idea may be killed in dressing it up, and it seems to us that the desire of so many gentlemen to be identified with a proposed department consisting of forty-five advisory chiefs will render it obnoxious to Congress. Any such irridescent dream as this will not appeal to practical legislators. The very first expression that rises to the lips of the average congressman in connection with this matter is to refer to the excellent work already being done by the Marine Hospital service, and to desire to understand what things are necessary to be added to its powers to make it all that is sought in the Spooner bill. It is the prudent view of every reasoning man in Congress to use existing instruments in this bureau as the basis of any legislation, and uniformly to consider how this bureau can be developed for the purposes named. The action of the New York Chamber of Commerce and the Academy of Medicine in indorsing the Spooner bill seems to us to have been taken without a consideration of these important facts. No department of the government has ever been made at one sitting of Congress. Departments are the developments of bureaus, and the failures heretofore on the part of the medical profession in seeking an ideal have been due to the fact that it has not been in touch with the practical views of legislative conditions. While it has aimed at the stars it has fallen into the mire. It seems to us not an example of professional etiquette, professional fraternity, for any medical association to array

itself officially against members of the profession already engaged, as the officers of the Marine Hospital service are, in professional work, by endeavoring to condemn them or obliterate them by hostile legislation. There is no recorded evidence of their failure or neglect to perform their duties properly and efficiently with the means at hand; and while certain persons have, for one reason or another, whose motives we do not care publicly to criticise, sought to humiliate and injure them by the advocacy of the Spooner bill, such opposition must be accepted for what it is worth. It seems plain to us that this corps has the confidence of Congress and the people with whom it is brought in contact. The evidences of this are so numerous that it seems trite to refer to them. We need only instance the hue and cry raised about the management of Ship Island, when it was claimed that a great and indignant public would demand its being removed from the face of the earth and the management consigned to everlasting obloquy. Two independent investigations were had—one by the senate of the United States and the other by the legislature of Mississippi, both of which bodies not only unanimously approved its existence and continuance, but applauded its management. That which was to be the great rallying-point of the opposition has vanished into thin air. So we regard the position assumed by the Chamber of Commerce and Academy of Medicine as a mistaken one: whereas, had they joined hands in support of the movement to develop the Marine Hospital service by gradual growth into the national health organization, which is desirable, better results would undoubtedly be seen at this time.

Gentlemen may cry that no harm is intended to the Marine Hospital service in the enactment of the Spooner bill; yet if any one will read it and observe how everything, from the building to the waste baskets, is turned over to the proposed new organization, he will get a faint idea as to the real meaning of the measure.

THE HEALTH-BOARD BILL.

The Brush bill, amending certain provisions of the charter as to the board of health, is still delayed in the senate cities committee, the impression being that the only objection now urged to the passage of the bill is the announced policy of the administration not to pass at this session any bills amending the charter. Such a general policy may be a wise one, but exception ought to be made in favor of this health bill. Among other things of imperative importance, the bill in its present form seeks to repeal sections 1,248 and 1,249 of the charter. No practising physician in the city who takes the trouble to read these sections will hesitate for a moment to exert all his influence urging an immediate repeal of such extraordinary and unjust and unwise statutory provisions. Section 1,248 empowers the department of health to require of any physician, not less than three hours after service of a demand therefor upon him, an affidavit, stating therein whether he has or has not any patients who, in his opinion, shall then be sick of a pestilential, contagious, or infectious disease, and, if he has any such patient, to state in such affidavit his or her name and the house or place in said city where he or she shall then be, and the nature or name of such disease, to the best of his knowledge and belief. Section 1,249 makes the refusal or neglect to comply with the foregoing provision a misdemeanor, and subjects the physician to a penalty of $250, and furthermore makes it the duty of "each visiting, hospital, and consulting physician" to make an immediate report to the health department of the name of every practising physician by whom he shall have reason to believe the provisions of section 1,248 have been violated; and the law then reads: "And if such physician shall neglect or refuse to perform his duty, the department shall order him to be suspended from any office he may hold, and he shall moreover be liable to such further penalty, and to such prosecution for his violation of this law and of his duty, as the board of health shall determine." Probably no such extraordinary delegation of legislative power as this has ever before been attempted in any American State. An executive department is empowered by the legislature to impose any penalty it may see fit! The consideration that such a provision is probably incapable of enforcement if resisted is no sufficient reason for permitting it to stand as part of a statute. Despotic as must be, for emergencies, the powers of health boards, such powers should not be rendered nugatory when the emergency does come by being plainly and flagrantly unconstitutional; nor should physicians be subjected to the humiliating position of being compelled to act as spies upon the professional conduct of those who call them in consultation.

It is quite true that great difficulty has been experienced on the part of the health board in getting full and adequate reports as to the existence of contagious disease. The same thing can be said of the difficulties which generally attend governmental departments in getting adequate proof of the commission of crime. Substantially all the arguments which can be urged in support of a law compelling physicians to disclose confidential information acquired by them in the treatment of their patients would apply to a law enabling the police department to require affidavits from priests and ministers of religion setting forth the information got by them in the course of their ministrations, as to the commission of crime. This subject has long and frequently been a matter of discussion, and long ago it was found to be for the public welfare that confidential communications of this kind should be sacred. The code of civil procedure still contains the provision prohibiting a physician from disclosing information acquired by him in the treatment of a patient, except with the consent of the latter, or, after his decease, with the consent of his legal representatives. Wholly apart from any statute, the honor of the profession has long made such matters sacred. Such information as the interests of the public require to be given to governmental officers can be given, for all purposes of sufficient efficacy, without disclosing the particulars called for by section 1,248. Every physician knows that there are very many ailments which

are undoubtedly technically contagious, but which are not ground for apprehending anything like an epidemic. Every physician knows that there are multitudes of patients who will seek no medical advice, but will trust to the ministry of quacks and charlatans, if they know that the particulars of their physical conditions are liable to be spread upon the records of the city government. The information conveyed in such an affidavit would be a fruitful temptation to blackmail. It is probably safe to assume that of reputable physicians nine out of ten—indeed, we are inclined to say, ten out of ten—would take their chances of prosecution, by declining to furnish an affidavit of this description if called upon to do so. After all, the public health depends vastly more upon the aggregate individual efforts of physicians in preventing disease and in curing disease than it does upon any public or executive agency. It is a great mistake for health laws to create antagonism between the medical profession and the health boards. In the long run, the latter must depend for efficient service upon cordial co-operation from the rank and file of the profession. Senator Brush's bill should therefore be expeditiously passed, even if it contained no other features than the repeal of such obnoxious provisions as the two sections of the charter above referred to.

THE STATE MEDICAL SOCIETY AND LOCAL MEDICAL LEGISLATION.

Among the objections raised to the Brush bill, the following letter, contained in the brief of the health board, deserves more than passing notice:

"New York, February 8, 1898.

"*Nathan Straus, Esq., President Health Department.*

"Dear Sir: Notwithstanding the indorsement of the Medical Society of the County of New York, of which I am a member, I believe the majority of medical men are opposed to Senate bill No. 5. That I am opposed to it personally I am free to admit, and if I can aid you in securing its defeat I trust you will consider me, in my official capacity, as yours to command.

"Very truly yours,

[Signed] "Frank Van Fleet, M.D.,

"*Chairman of Committee on Legislation, Medical Society of the State of New York.*"

We feel that the matter is one to which public attention should be called, especially the attention of the officers of the Medical Society of the State of New York. Either Dr. Van Fleet is acting under the authority of that society, or he is not. If not, it would seem to us that the president of the society should curtail his activity; but if he has the sanction of the State Medical Society, it certainly appears to us to be a little derogatory to the dignity of the society thus to place itself subject to the command of the health department of this city. And why should the State Society meddle with legislation that affects our county only and which has received the approval of our County Society? We await an explanation.

MORE SANITARY LEGISLATION.

Assembly bill 969, introduced February 18th by Mr. Mullaney, reads:

"An act in relation to the inspection of cold-storage warehouses by boards of health in cities of the first class.

"Section 1.—The board of health of a city of the first class shall appoint not more than four inspectors of cold-storage warehouses, whose duty it shall be to inspect and examine all buildings used as cold-storage warehouses in such city, and all food supplies stored therein which are perishable, such as meats, poultry, eggs, butter, and cheese. Such inspectors may be removed for cause. Their compensation shall be fixed by the board, and shall be paid in the same manner as are other charges against such board."

Sections 2, 3, 4, 5, and 6 refer to manner in which these inspections should be carried out.

The bill, as a whole, is ridiculous. Meats are rarely put in cold storage, while game and fish, which are so stored, are omitted from the provisions of the bill. None of these articles, however, can be properly examined in cold storage, and the regular inspectors are amply capable of taking care of articles improperly offered for sale, whether they have or have not been in cold storage. The whole purport of the act seems to be simply to provide four additional officials to draw money from the public purse, or help to build up a political machine.

Mr. Haight on February 23d introduced into the assembly bill No. 1,060, entitled:

"An act to protect the public health by forbidding the sale of goods in second-hand packages," the first section of which reads as follows:

"It is hereby declared to be unlawful for any vendor of goods to put the same up for sale, offer for sale, or sell the same put up, in any bottle, can, box, or other package that has before been used as a package or covering for the same or other goods. But this act shall not prohibit the use by farmers and gardeners of crates or other receptacles for conveying their products to market."

This, if it became a law, would prevent the housewife from sending her oil can to the grocer for a fresh supply of kerosene, for surely kerosene is goods that are held for sale and the oil can is a second-hand package.

Many salt dealers purchase large sacks of salt from the manufacturers, and repack the salt in smaller bags, returning the old ones to be refilled. This would also be prohibited, and if new packages were required it would add from two to three dollars a ton to the cost of the goods. Fertilizers for farmers' use are also frequently packed in sacks which have been used before, and so of many other articles. This is certainly a piece of fool legislation which it is sought to enact under the plea of looking out for the public health.

Duke Charles Theodore of Bavaria is reported by cable to be operating for cataract upon all the Arabs of the desert in the neighborhood of Biskra in Algeria, where he is passing the winter.

News of the Week.

A Bequest to the Jefferson. — The will of Dr. Francis W. Shain, late of Jersey City, filed for probate in Philadelphia recently, bequeaths $7,000 to Jefferson Medical College in that city, $3,000 as a fund for prizes, and the remainder as a fund for two scholarships open to competition by white male graduates of the Philadelphia public schools.

Removal of the Stomach.—A telegram to the daily papers from San Francisco announces that a surgeon of that city made a complete excision of the stomach, on February 25th, of a female patient suffering with cancer. Thirty-six hours after the operation the woman was reported to be resting comfortably, with almost a normal pulse and temperature.

A Change in the New York Board of Health.—Mr. Nathan Straus, who was appointed president of the health board by Mayor Van Wyck on January 1st, resigned the office a few days ago, alleging as the reason for his act the pressure of private business. The resignation was accepted immediately, and the mayor appointed Michael C. Murphy, a Tammany district leader, to be Mr. Straus' successor.

The Skin and Cancer Hospital.—The new building of the New York Skin and Cancer Hospital was dedicated on Saturday afternoon, March 5th. Addresses were made by Drs. A. Jacobi and L. Duncan Bulkley, and a prayer was offered by the Rev. Dr. William Grosvenor. The building is on the northeast corner of Second Avenue and Nineteenth Street, and is a four-story, fire-proof, brick structure. In the basement are all the appliances necessary for the carrying out of hydrotherapeutic measures, and also the laundry, kitchen, and dining-rooms. On the first floor are the consultation-rooms, dispensary, reception room, and office. The men's and women's wards for skin diseases are on the second floor. There are six beds in the former and fourteen in the latter. There are also two private rooms on this floor. On the third floor are the cancer wards. The children's ward is on the fourth floor, and there are also six private rooms on this floor, beside the operating-room. All of the latest and most approved appliances for hospital work are provided in this building. There is room for about one hundred beds in the building. The doctors' and nurses' quarters are in an adjoining house.

An Alleged New Epidemic in India.—It is reported that an epidemic of "black blister" has broken out at several places in central India, the number of deaths from the disease averaging fifty a day.

The Queen of Portugal is a frequent subject of newspaper paragraphs, some alleging that she is a trained nurse, others that she has discouraged the use of corsets by taking Roentgen-ray views of the figures of her ladies in waiting, and others again that she is a graduate in medicine. Concerning the last statement, a French medical journalist wrote to the lady, requesting details as to her professional career, and received a reply from the chamberlain to the effect that Her Majesty had never studied medicine and took a purely humanitarian interest in the progress of that science.

German Congresses.—The twenty-seventh congress of the German Surgical Society will be held this year in Berlin, in the Langenbeckhaus, from April 13th to the 16th, under the presidency of Prof. F. Trendelenburg, of Leipzig. In connection with the congress there will be an exhibition of preparations, instruments, etc., and a display of Roentgen photographs. The seventeenth congress of internal medicine will be held at the same time at Wiesbaden.

Mr. Gladstone's Health is reported to have improved greatly since his return from Cannes. His daughter says that he is more vigorous in movements than for some time, his voice is strong and clear, and his mental capacity and appetite for work are as keen as ever. As this improvement has come since the invalid went to Bournemouth, on the south coast of England, it is regarded by many as a strong argument in favor of home resorts and against the Riviera.

The Late Dr. John G. Truax.—At a meeting of the Mott Memorial Library, Thursday, March 4, 1898, the following resolution was passed:

"*Whereas*, It has pleased Almighty God in His infinite wisdom to remove from our midst our president, associate, and friend, John G. Truax, M.D., we desire to place on record our appreciation of his character, and gratitude for the services that he has rendered to this institution. Therefore be it

"*Resolved*, That, in the death of John G. Truax, M.D., this institution has lost a most faithful officer and president, one who was ever ready by advice and action to advance its interests in all useful directions, and in whose management of its finances had exercised such diligence and faithfulness. And be it further

"*Resolved*, That we, his sorrowing associates, do hereby grieve and mourn the loss we have sustained, and that, while we bow in submission to the will of our heavenly Father, we lament the untimely death of our friend, cut off in the midst of his useful career; a friend who, by his upright example and Christian life, had become endeared to us all, and whose loss we shall feel in our personal and official connection.

"*Resolved*, That we extend to his family our heartfelt sympathy in their bereavement, and that a copy of this minute be sent them.

[Attest] "F. A. Baldwin, M.D., *Secretary*."

Obituary Notes.—Dr. Henry David Kahler, of Shelby, Ohio, died of renal trouble on February 20, 1898, aged thirty-two years. He was born at Bolivar, Ohio, and was a graduate of the Western Reserve Medical College in 1895. He practised medicine two and one-half years at Mineral Point, Ohio, and had recently located at Shelby, Ohio. He was a member of the Academy of Medicine of Canton, Ohio, and of the Northeastern Ohio Medical Society.—Dr. Jennie Taylor Gordan, a medical missionary of the Methodist Church and a niece of Bishop William Taylor, died at Malange, Angola, on December 29th. Her

husband was an African missionary, and her parents resided at Mechanicsburg, Pa. She lived for many years in Africa, and was noted among the natives of a wide extent of country for her medical skill.—Dr. di Pietra Santa, of Paris, editor of the *Journal d'Hygiène* and founder of the Society of Hygiene of Paris, died in that city recently. He was a native of Corsica, and was seventy-seven years old at the time of his death.

Due Credit to Medical Society of County of New York.—In the recent editorial on osteopathy, the credit for prosecuting quacks should have been given to the Medical Society of the County of New York and not the State Medical Society. The latter never does anything in that line, unless perhaps in an obstructive way.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending March 5, 1898. March 2d.—Surgeon F. W. F. Wieber detached from naval hospital, Norfolk, Va., and ordered to the *Miantonomoh*, March 10th; Surgeon G. P. Lumsden detached from special duty at Norfolk, Va., and ordered to the *Franklin;* Passed Assistant Surgeon B. R. Ward ordered to the *Katahdin*, March 1st; Passed Assistant Surgeon I. W. Kite detached from the *Franklin* and ordered to the naval hospital, Norfolk, Va.

Medical Students à la Française.—A dispatch to the *Evening Post* states that two thousand students of the Rush Medical College, the Chicago College of Dental Surgery, and the Marquette School engaged in a fight with forty policemen on February 8th. The trouble continued from noon until six o'clock in the evening. The police were compelled to send in riot calls repeatedly, and in the early part of the scrimmage they were badly worsted. When the students were finally put to rout, they retreated to the protection of the college buildings. From there they hurled down all kinds of missiles upon the police.

The Plague at Bombay.—According to a dispatch to *The Sun* the number of deaths in Bombay from the plague were 1,134 during the week ending February 10th, and from all causes 2,067. This is equivalent to a death rate of 129. The highest number of deaths in a single day were recorded on February 9th, when there were 348.

Examinations in Municipal Hygiene.—The trustees of Rutgers College in New Brunswick, N. J., have voted to institute examinations and grant certificates in municipal hygiene to officers of local boards of health, sanitary, factory, and plumbing inspectors, and those who may seek appointment to these places. The certificates will indicate the degree in which the holders are qualified to perform the duties relating to the promotion and the protection of the public health required by the laws of the State, and by the rules, regulations, and ordinances of local boards of health. The examinations, which will be held on the first Wednesday of the months of March, June, and October, will be written and oral, and open to both men and women. The subjects of the examinations will be plumbing, drainage, and sanitary construction; sanitary laws, ordinances, rules, and regulations; preventable diseases, isolation, and disinfection; nuisances and disposal of waste; and lighting, heating, ventilation, and food.

A Relapse.—Lady Henry Somerset, in a rational interval about a year ago, gave a qualified approval of the adoption of measures to prevent the spread of venereal disease among the British troops in India. She has now written to the secretary of state for India, stating that she desires "to withdraw her indorsement of any form or principle of state regulation of vice."

Menelek's Physician.—The ruler of Abyssinia has selected a Swiss medical woman, a graduate of the University of Zurich, to reside in his palace and act as family physician to his household.

A Chair of Physiological Chemistry at Columbia.—The authorities of Columbia University decided a short time ago to establish a chair of physiological chemistry at the College of Physicians and Surgeons, and have called Prof. Russell H. Chittenden of Yale to occupy it. It is said that he has accepted the invitation, retaining also his place at New Haven.

An Impertinence.—A newspaper printed in Spokane, Wash., has announced its intention to "publish the name of the attending physician in each case where the patient dies." The language of the announcement is somewhat ambiguous, yet the purpose is sufficiently intelligible to enable it to be characterized as colossally impudent.

The Pipe Face.—It is declared that the constant habit of smoking pipes has a perceptible effect upon the face. "The pressure of the lips to hold the pipe in position increases the curvature of the lips round the stem and the muscles become more rigid here than in other parts. Thus the lips at a certain point become stronger, and the pipe is unconsciously held in the same habitual position. After long continuation of the habit, small circular wrinkles form parallel with the curvature of the lips around the stem These are crossed by finer lines caused by the pressure of the lips to retain the stem in position. In the case of old men who have smoked a pipe for years the effect upon the lips is very marked, not only altering the form of the lips but of one entire side of the face, causing the wrinkles that are the result of age to deepen, and, instead of following the natural course of facial wrinkles, to change their course so as to radiate from the part of the mouth where the pipe is habitually carried. Furthermore, one or both lips often protrude, just like the lips of people who used to suck their thumbs when children. The effects of pipe smoking upon the teeth and lower jaws are even more apparent than in the case of the lips. If any man who has smoked a pipe for a considerable length of time will take the trouble to examine his own teeth, he will find that at the point where he usually holds the stem between his teeth the latter have become worn.

Reviews and Notices.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities in Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In Twenty Volumes. Vol. XII.: Mental Diseases, Childhood and Old Age. New York: William Wood and Company. 1897.

The writings of five men only are represented in this issue of Stedman's interesting series of modern monographs. The title is slightly confusing and might lead to the conclusion that the volume was devoted to mental diseases as they affect the very young and very old. Such is not the case.

The first chapter, by Dr. G. Fielding Blandford, lecturer on psychological medicine at St. George's Hospital, London, England, contains two hundred and fifty-four pages, and while it is true that the insanity of childhood comes in for a share of attention, just as does senile insanity, that of puberty and that of adolescence are likewise considered. A most interesting subdivision is that treating of insanity from the standpoint of its exciting cause in the various diseases, syphilis, rheumatism, gout, sunstroke, poisons, alcohol, anæmias, kidney diseases, diabetes, myxœdema, cardiac, digestive, uterine affections, etc. In his treatment of the various forms of mental unbalance, the author has made a most readable contribution.

"Idiocy" comes next, with one hundred and twelve pages, written by Paul A. Sollier, of the University of Paris. For a dry subject and a rather hopeless condition, the author has made the best of it one could perhaps expect. "Criminal Anthropology" claims the attention from a threefold cause. The chapter is short and most entertaining; it is attractively illustrated, and the author is Cesare Lombroso, professor of legal medicine and psychiatry at the University of Turin. Now comes "Old Age," neglected in medical works as it too often is in real life. The editor presumably meant no irony in his choice of an author whose name suggested youth. Dr. J. Boy-Tessier, physician to the hospital for old people in Marseilles, has given an excellent account of senile conditions and modifications of disease processes as they occur in advanced years. Too little space, it seems to us, is devoted to the cutaneous alterations due to age, including the skin epitheliomata.

"Diseases of Children," exclusive of infectious disease, (which is a lengthy chapter in itself) and rachitis, have received adequate treatment in the hands of Dr. Jules Comby, physician-in-chief of the Hôpital Trousseau, Paris. The author, who is well known as editor of *La Médecine Infantile* and by his many contributions to the literature of children's diseases, has given in about three hundred pages a concise account of most of the affections peculiar to or frequent in the young. The essentials of diagnosis and treatment are given with brief reference to pathology and etiology, while lengthy descriptions are omitted. More attention is given in this chapter to skin affections than one would expect to find in so general an article. Considered as a whole, this is one of the best volumes of the encyclopedia, in that it embraces much not usually found in works of the day and covers a wide range of subjects of interest and importance to the general practitioner.

A Pictorial Atlas of Skin Diseases. From Models in the Saint Louis Hospital, Paris; with Explanatory Woodcuts and Text. By Ernest Besnier, A. Fournier, and others. Edited and annotated by J. J. Pringle, M.D., F.R.C.P. London: The Rebman Publishing Company, Limited. Philadelphia: W. B. Saunders. 1897.

The last fasciculus (Part XII.) has arrived to complete the volume. Two of the plates are devoted to chancres, the figures representing different appearances as the primary lesion occurs upon the tongue, tonsil, lips, and nasal fossa. The other plates show in a fairly satisfactory manner instances of urticaria pigmentosa, with atrophic spots arranged in transverse bands; impetigo contagiosa, in which the cheek and ear are involved in yellow-crusted lesions; xeroderma pigmentosa, or, as it is entitled on the plate, xerodermia pigmentosa. It would be well if dermatologists could conform to such designations as would not too much confuse the non-specialist by sudden changes in gender and endings of qualifying adjectives. The work taken as a whole has not contained enough of the every-day cases to supply the needs of the average purchaser of medical publications. The text has been for the greater part descriptive of the case in hand, and the field of dermatology covered is thus quite restricted. It is, however, an interesting and, up to a certain point, an artistic work, and well calculated to make one desire to see the wax-model collection from which the pictures have been selected. The translation and English editorship leave nothing to be desired.

Compressed-Air Illness, or So-called Caisson Disease. By E. Hugh Snell, M.D. London: H. K. Lewis. 1896.

This may be looked upon as the standard work on the question of diver's paralysis and allied effects of caisson pressure.

The author shows familiarity with the condition from a practical experience which has not been lacking in scientific observation. The book is well worth reading, and its recommendations will be found of interest to all who have charge of workmen in tunnel or bridge building and similar occupations.

A Practical Treatise on Diseases of the Skin. By John V. Shoemaker, M.D., LL.D., Professor of Skin and Venereal Diseases in the Medico-Chirurgical College and Hospital of Philadelphia, Physician to the Philadelphia Hospital for Diseases of the Skin. Third Edition, Revised and Enlarged. New York: D. Appleton & Co. 1897.

It is five years since we reviewed in these columns Dr. Shoemaker's second edition, and it must be taken as an index of merit that in these days of rapid multiplication in atlas and text-book literature in this department any work can run through more than one or two editions. The pictures are not so pleasing, in all instances, as others we have seen, and the text does not embrace so much of the deeper scientific stamp and fulness of histological detail of description as are found in some recent works. There is, however, a pervading spirit of therapy, in which the personality of the author is strongly brought out. This is, perhaps, the secret of the book's success. Probably in this field more than in many others a need is felt for definite plans of medication, and Dr. Shoemaker supplies the want to the reader's satisfaction.

A Text-Book of Practical Therapeutics. With Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc. Sixth Edition, Enlarged, Thoroughly Revised, and Largely Rewritten. Philadelphia and New York: Lea Brothers & Co. 1897.

The popularity of this work, already familiar to the readers of our review column, is well attested by the issue of the present revised edition.

There would seem to be an especial call in America or among English-reading book buyers for condensed, concise, already digested medical information. It is quite evident that large portions of the work have been rewritten and thus brought up to the requirements of changing views in therapeutic matters. It has been the author's intention that this work on drugs and treatment should be most usefully employed in conjunction with his other work on "Practical Diagnosis." It is, however, entirely independent of the latter. That the work is eminently practical goes without saying. It is not exhaustive; it deals more with well-attested than with the newest remedies, and the still doubtful methods, as, for example, serum therapy, are practically left out.

Incompatibilities in Prescriptions. For Students in Pharmacy and Medicine and Practising Pharmacists and Physicians. By Edsel A. Ruddiman, Ph.M., M.D. New York: John Wiley & Sons. 1897.

After considering incompatibility of drugs from the pharmaceutical side, the author gives a long list of prescriptions of faulty construction. These are then taken up by number (reference being thus made easy) and criticised, the error being pointed out and explained. There are many prescriptions given which one would never think of writing, but by a study of the whole one may learn what not to do. It is, obviously, a work of more necessity to the compounder than to the prescriber.

A Text-Book of the Diseases of Women. By Henry J. Garrigues, A.M., M.D., Professor of Gynæcology and Obstetrics in the New York College of Clinical Medicine; Gynæcologist to St. Mark's Hospital; Gynæcologist to the German Dispensary; Consulting Obstetric Surgeon to the New York Maternity Hospital, etc. Containing 335 Engravings and Colored Plates. Second Edition. Thoroughly Revised. Pp. 728. Philadelphia: W. B. Saunders. 1897.

It is with especial pleasure we welcome the appearance of a second edition of this work by our esteemed fellow-townsman. The best commentary on the book is the fact that since its publication, three years ago, it has by the sheer force of its intrinsic merit shouldered its way, through a crowd of more ambitious works, up to the front rank. Doubtless the author's reputation for sound learning and careful statements has had no little to do with the confidence which has been reposed in the product of his study and experience, aside from its peculiar features of excellence.

In announcing that he has thoroughly revised the first edition, we feel assured that no ordinary care has been exercised in correcting faults and adding new matter. There is so much to praise in the work of revision that we may be pardoned a few criticisms from the standpoint of the teacher and general practitioner.

In the third edition we feel sure that students and teachers of medicine would welcome an attempt at condensation, by the omission of many unimportant details in the way of rare "diseases" and operations of interest only to the inventor. Moreover, though the erudition and exhaustive research of the author are shown by the copious footnotes, constant reference to conditions and complications of interest only to the specialist is apt to divert the mind of the beginner from the main issues. Instruction of the student in gynæcology (and of the practitioner, for that matter) cannot be too elementary. His tendency to diffuse reading must constantly be checked until he has digested the most important facts. For example, under the head of "Diseases of the Perineum" (why "diseases," instead of injuries?) we find descriptions of half a dozen operations, one of which, to our certain knowledge, was abandoned by its inventor almost as soon as it was published. Why not teach the student one or two good methods —Hegar's, if you will—and let him become proficient in that? The tyro who is always uncertain as to what new method he had better try can never hope to attain success as a surgeon. These faults prevent even this edition from being an ideal text-book, and we confess to a slight feeling of disappointment that they were not corrected.

The chapters on diseases of the uterus, tubes, and ovaries have been brought thoroughly up to date, and the careful descriptions of modern aseptic technique are unsurpassed in any book in our language.

If one were allowed to peruse only the index and table of contents and to glance at the footnotes, he would be forced to the conclusion that the work was that of a scholar.

Hugh Wynne, Free Quaker. By S. Weir Mitchell, M.D., LL.D. In Two Volumes. New York: The Century Company. 1897.

This is a tale of the Revolution and chiefly of the exciting part taken therein by a young Quaker whose nature from the beginning cried out against the doctrine of his church in regard to non-resistance and the suppression of all emotion or expression of any, even the strongest of human passions. Dr. Mitchell has written much in prose and verse outside of medicine, but good as his work has been it has never until now been of such excellence as to expose his medical reputation to the danger of being eclipsed by his literary fame. But with the appearance of Hugh Wynne the author steps on a distinctly higher plane, where, in actual story telling at least, he appears to much greater advantage than he did in some of his previous works, such as "When All the Woods Are Green," in which the reader got much philosophy indeed, but with a very thin thread of a story. In this latest book Dr. Mitchell has a good story to tell and he tells it well. The narrative runs rapidly and smoothly, the interest being maintained unabated to the end, and the portraiture of character is strong and clear. Of special interest to medical readers is the way in which, by a few strokes here and there, the character of Dr. Rush is made to stand out in the open—a character not altogether lovely, yet, as human beings go, a really noble one.

Saw Palmetto. Its History, Botany, Chemistry, Pharmacology, Provings, Clinical Experience, and Therapeutic Applications. By Edwin M. Hale, M.D., Author of "New Remedies," "Practice of Medicine," etc. Philadelphia: Boericke & Tafel. 1898.

We do not presume that the author intended this in any sense as a humorous work, but some portions are open to such a construction. After a consideration of the plant and its chemical qualities we come to provings by Dr. Boocock, who "had before commencing a scalding feeling on passing water," and "slight glueing of the meatus." He does not say if gonococci were still present, but the supposition must be that they were. This is a point of importance as bearing upon the value of the subsequent proving-sensations.

After two drops of the tincture three times daily, he says, "embracing was very satisfactory, and my partner wanted to know what made me so fierce; the work was very good . . . as it used to be with me thirty or forty years ago."

The effects produced by an increase to five drops point to the drug's becoming popular with octogenarians. The provings by women show some unfavorable effects upon the breasts and ovaries. The author has given a very good account of the Sabal serrulata, but the reports of the provers quoted are not convincing. He deprecates the use of the much-advertised compounds.

The Rubáiyát of Doc. Sifers. By James Whitcomb Riley. Illustrated by C. M. Relyea. New York: The Century Company. 1897.

The picture which the author of these delightful verses draws of the country doctor is one most flattering to our profession, even though it be an impossibly perfect man whom he portrays. "Doc. Sifers" is a kindly, ready, cheerful, all-round family physician; charitable, gentle, a lover of children, an inventor of all sorts of ingenious contrivances, a detective, a hunter, a fisherman, ex-army surgeon, patriot, profoundly religious though of most unobtrusive piety, a settler of quarrels, and a leader in his community. All this described in James Whitcomb Riley's happiest effort at dialect verse, so simply and so vividly that as we read we forget that no man was ever quite so perfect, and we end by loving Doc. Sifers as if we too were among his patients.

Outlines of Rural Hygiene. For Physicians, Students, and Sanitarians. By Harvey B. Bashore, M.D., Inspector for the State Board of Health of Pennsylvania. With an Appendix on the Normal Distribution of Chlorine, by Prof. Herbert E. Smith, of Yale University. Illustrated. Philadelphia, New York, and Chicago: The F. A. Davis Company. 1897.

This is a little work that will be of real practical value to all dwellers in small towns or the open country, by laying bare before them their most flagrant sanitary sins and those of their neighbors, and pointing out to them the remedy for resultant evils. The book contains chapters on water supply, waste disposal, the soil, habitations, and disposal of the dead, and an appendix on the normal distribution of chlorine. The work should have a wide circulation, and might profitably be distributed as a tract by sanitary societies or State boards of health throughout the farming-districts of the country.

Skin Diseases of Children. By George Henry Fox, A.M., M.D., Clinical Professor of Diseases of the Skin, College of Physicians and Surgeons, New York; Physician to the New York Skin and Cancer Hospital, etc. New York: William Wood and Company. 1897.

This is in book form a series of illustrated articles (twelve photogravures and chromographic plates and sixty illustrations) on certain skin diseases which are apt to occur in infancy and childhood, which appeared a year ago in the *American Journal of Obstetrics and Diseases of Women and Children*, published by the same firm. Some additions, the author says in his preface, have been made, but he disclaims any attempt to present a complete work on the subject. As a sketch of the commoner forms of eruption it is very acceptable. In the letterpress proper, exclusive of formulæ, there are less than one hundred pages. When the picture space is deducted it is seen that little text is left. The pictures are, however, in many instances admirably executed, and reflect credit upon the reproducer no less than upon the photographer. Others leave much to be desired

both in lack of finish and in imperfectly representing the disease intended. This criticism is true, however, of all collections of pictures of skin diseases so far published.

It is a very nice book to have in one's collection, but not one from which the differential diagnosis of infantile and children's eruptive diseases can be mastered.

CHRISTIAN GREECE AND LIVING GREEK. By DR. ACHILLES ROSE. New York: Peri Hellados Publication Company. 1898.

THE indefatigable champion of modern Greece, the modern Greeks, and modern Greek, Dr. Achilles Rose, of New York, has here published in collected form his many writings in support of the noble cause which he has espoused. The chapters are headed: An historical sketch of Greek, the proper pronunciation of Greek, the Byzantines, the Greeks under Turkish bondage, the Greek war of independence and the European powers, the kingdom of Greece before the war of 1897, and Greek as the international language of physicians and scholars in general. Most of these have been delivered in the form of lectures before various medical and other societies in this city. They bear evidence of the author's diligent reading and of his fervent love for his unhappy protégés, and their musical and ancient tongue.

PRACTICAL TOXICOLOGY FOR PHYSICIANS AND STUDENTS. By PROF. DR. RUDOLF KOBERT, Medical Director of Dr. Behmen's Sanatorium for Pulmonary Diseases at Gorbersdorf, in Silesia (Prussia); Late Director of the Pharmacological Institute, Dorpat (Russia). Translated and Edited by L. H. FRIEDBURG, Ph.D. Authorized Edition. New York: William R. Jenkins. 1897.

THE author has been led to edit the tables and brief text of this practical work giving an idea of "toxicology at a glance," by the demand on the part of his students for the separate tables which he has long used in his lectures.

It is a work well suited for those who have not the time to go into the more exhaustive treatises on poisons.

The appendix contains much useful information on animal and vegetable esculents, auto-intoxications, and a list of reagents known by the name of their discoverer.

THE PRESCRIBER. A Dictionary of the New Therapeutics. By JOHN H. CLARKE, M.D., F.R.C.S., Ext. Mem., Royal Medical Society, Edinburgh, etc. American Edition Revised and Enlarged by the author from the Fourth English Edition. Philadelphia: Boericke & Tafel. 1898.

TO the revised edition which appeared in England in 1893, the author has added references to many of the newer preparations.

After instructions as to care taking and prescribing, a list of abreviations and signs is given; then diseases are taken up in alphabetical order, with the homœopathic indications for medication. The glossary, beginning on page 250, presupposes a pitiful lack of knowledge on the reader's part.

INTERNATIONAL CLINICS. A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment. By Professors and Lecturers in the Leading Medical Colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by JUDSON DALAND, M.D. (University of Pennsylvania), Philadelphia; Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania, etc.; J. MITCHELL BRUCE, M.D., F.R.C.P., London, England, Physician to and Lecturer on the Principles and Practice of Medicine in the Charing Cross Hospital; and DAVID W. FINLAY, M.D., F.R.C.P., Aberdeen, Scotland, Professor of Practice of Medicine in the University of Aberdeen, etc. Volume III. Seventh Series. Philadelphia: J. B. Lippincott Company. 1897.

IN some respects this book of lectures which comes to us four times a year is improving. Not only has the attractiveness of the outside been increased by a change in binding, but the class of contributions is being rather more than well sustained. On the other hand, the illustrations of the present volume do not compare favorably with those in the 1895 series. Nine of the thirty-seven contributors are Philadelphia physicians; still, France, England, Austria, and Scotland are all well represented, while a few stray lectures come from Chicago and New York. The introduction of short articles on treatment, specially prepared but not in the form of lectures, is a good feature, but these should be kept within the bounds of brevity.

AMBROISE PARÉ AND HIS TIMES, 1510–1590. By STEPHEN PAGET. New York and London: G. P. Putnam's Sons, Knickerbocker Press. 1897.

WE find in this neatly printed and interestingly illustrated volume of over three hundred pages the history of Paré's life and times.

This is a story so interwoven with romance and adventure that the drier and more strictly professional parts are pleasantly enlivened. The accounts of journeys undertaken are filled with interest, and what one learns of Paris in Paré's time is worth the while. The frontispiece is a reproduction of a portrait of Paré at the age of sixty-five.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 3, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

Memorial Address on Dr. Joseph O'Dwyer.—The meeting being in charge of the section on laryngology and rhinology, and the subject chosen being "Intubation," the scientific papers were preceded by a memorial address on Dr. O'Dwyer, by DR. W. P. NORTHRUP (see page 361).

Intubation in Diphtheria.—DR. WILLIAM K. SIMPSON read this paper. He said that one of the great advantages of intubation, and one which placed it in sharp contrast with tracheotomy, was its simplicity and its freedom from the horrors of the latter operation. It was for this reason that intubation had been so promptly resorted to, and it probably explained in part the brilliant results attained. It had now been proved that sixty per cent. of laryngeal cases in the course of diphtheria did not require intubation if reliable antitoxin was administered early. If, however, croup did supervene, the antitoxin should be continued and the croupy symptoms watched, it being remembered that it sometimes took twenty-four hours for the full effect of antitoxin to become manifest. While the antitoxin effect was being awaited, if stenosis became marked intubation should be performed. Before the introduction of antitoxin the tube usually remained in six or seven days, but the average time with antitoxin was about three or four days. Personally, he preferred to leave the tube in a maximum of five days in private practice, when the physician was not always at hand to reintroduce it, should it be found that it had been extracted too early. Undoubtedly in many cases the tube could be removed earlier without the necessity for a reintroduction. The chief indications for its removal before this time were severe discomfort and pain from pressure, severe attacks of coughing and sudden stenosis, due to membrane blocking up the tube. This last accident might occur earlier in antitoxin cases, because of the tendency for the membrane to exfoliate earlier.

Prolonged Retention of the Tube.—In certain cases the stenosis became permanent, requiring the prolonged retention of the tube. The best exposition of this rather obscure subject had been presented in a paper published last year by Dr. O'Dwyer, who said that the causes could be summed up in a single word —"traumatism." The injury to the larynx was done by a tube which did not fit, or from an imperfectly constructed tube, or from the use of too large a tube, or one which was rough.

Introducing the Tube.—The most important point in the technique of intubation was, perhaps, to see that the patient's head was not tilted or the neck

twisted, and that the instrument was kept well in the median line. Its successful introduction was almost invariably followed by immediate relief in the breathing. The indications that the tube had been successfully introduced into the larynx were: 1, the relief of the dyspnœa; 2, the characteristic type of cough, which immediately took place, and which was moist and metallic. If this cough was not present, it was well to excite cough by giving the patient a drink of whiskey. It very rarely happened that the tube was obstructed by membrane at the time of its introduction. The accident was more apt to occur late in cases of croup, when the membrane had begun to exfoliate. If for any reason the breathing was not relieved, the tube should be removed by the string, which was at first secured over the ear, and the child then made to cough before the reintroduction of the tube. One accident which might happen was pushing the tube to one side into one of the ventricles. It could be avoided by keeping the tube in the median line during its introduction. Sometimes the tube was introduced into the œsophagus. This would be indicated by failure to relieve the breathing, by coughing, and by the string being pulled backward into the mouth in the efforts to swallow. The tubes that had been swallowed had usually been passed out of the rectum in from two to four days.

Extraction of the Tube.—The operation of extraction was more difficult than that of introducing the tube, and required a finer sense of touch. Before the extractor was used, the set screw should be so adjusted that the jaws of the instrument could not open more widely than was necessary for the removal of the size of tube in use. Attention to this detail would save much unnecessary traumatism of the larynx and adjacent structures. Extraction by pushing the tube out from below without the aid of any instrument might be successfully done in cases of emergency even by the nurse, and also occasionally in cases in which unusual difficulty was experienced in the use of the extracting instrument. To extract the tube from the larynx without an instrument, the patient was slightly inverted and the mouth opened; then the thumb was placed in the episternal notch, and the tube was pressed up into the mouth, where it could be seized with forceps or with the fingers. After the removal of the tube the patient should not be left until it was evident that there would be no immediate return of the stenosis.

Feeding after Intubation.—The child was best fed after intubation by the Casselberry method, the child's head being held down and the feeding done with the help of an ordinary "duck" feeding-cup. The food should be fluid or semisolid.

Prognosis.—The prognosis of intubation under the combined treatment, *i.e.*, intubation and antitoxin, was remarkably favorable; the recoveries being now from twenty-seven to thirty-one per cent., as against fifty-nine to seventy-five per cent., the former rate.

Intubation in Chronic Stenosis.—Dr. D. Bryson Delavan read this paper. He said that O'Dwyer not only invented but perfected intubation. Notwithstanding the excellent work of many others, it would be found that almost all of their important suggestions had been forestalled by the inventor of intubation. This was pre-eminently true regarding the intubation treatment of chronic laryngeal stenosis. It was now twelve years since intubation was first employed in these cases, which had formerly been treated with great difficulty, and with but little success, by rapid intermittent dilatation. Two years later, Dr. O'Dwyer said that, had intubation of the larynx for croup proved to be a failure, he would still feel amply repaid for his trouble by the results already attained in the treatment of chronic stenosis. A considerable number of cases had been reported, both here and abroad, which were confirmatory of the view just expressed. In 1894, no less than twenty-four successful cases were reported. Up to 1896, about one hundred cases had been reported, most of them entirely successful. In the few instances in which complete success had not been obtained, it was evidently due to failure on the part of the operator to understand the method, or else to a faulty application of the same.

Where it Succeeds.—Intubation was effective in the following conditions: 1, cicatricial stenosis due to injuries to the soft parts of the larynx; 2, narrowing of the space above and below the cords by simple, tuberculous, or syphilitic inflammation; 3, in cases in which tracheotomy had been performed, and in which, the tracheal cannula having been worn for a considerable time, the upper part of the trachea was filled with granulations; 4, in a fair proportion of cases of papilloma of the larynx: 5, in deformities of the larynx from injuries to or disease of its cartilaginous framework; 6, in ankylosis of the cricoid and arytenoid articulations, as in arthritis deformans of the same; and, 7, in various affections of the nerves of the larynx, *e.g.*, bilateral paralysis of adduction. In these cases it had been found that intubation acted as follows: 1, it relieved the urgent dyspnœa; 2, it promoted absorption by pressure; 3, it stretched contracted tissue and cicatricial bands and adhesions; 4, it caused forced motion of ankylosed articulations; and, 5, in cases of paralysis it brought about a separation of the vocal bands for a sufficient length of time to overcome the difficulty or admit of its treatment.

In 1892, the speaker said Dr. O'Dwyer had made the statement that in chronic cases intubation could be performed with greater ease by the aid of a laryngoscopic mirror. Dr. Delavan said that he had had several successful cases in his own practice. Only two weeks ago he had been hurriedly summoned to see a case of urgent dyspnœa in a woman in the Sloane Maternity Hospital, who was suffering from advanced pulmonary tuberculosis and was almost in the second stage of labor. With the assistance of Dr. W. H. Simpson, intubation was performed, and her dyspnœa had been relieved barely before the child was born.

Intubation for Acute Stenosis.—Dr. Charles H. Knight read this paper. He said that the brilliant results of intubation in diphtheria had almost obscured the usefulness of the procedure in other cases of acute stenosis. Thus, scarification was not always sufficient for the relief of œdema of the glottis. Here intubation seemed the ideal operation but for one thing, *i.e.*, the area of œdema might be so extensive as to overhang and obstruct one or the other orifice of the tube. As was well known, the upper part of the larynx was most affected by œdema, and this portion was most accessible to the knife. One authority had expressed his determination to perform intubation in future in the following conditions: 1, spasm of the glottis from any cause; 2, in bad cases of laryngismus in infants; and 3, whenever the presence of a foreign body in the trachea was suspected. In cases of injuries to the larynx, obstruction to breathing might follow in consequence of the formation of a hæmatoma, or of emphysema, or because of the presence of a foreign body in the upper air tract. Laryngismus stridulus usually led to general or local medication, so that the question of surgical intervention seldom arose. The number of recorded fatal cases did not exceed six or eight, but sometimes the distress and urgency were so great as to seem to justify such a simple procedure as intubation. Personally, he had used it in only one case of spasm of the larynx, occurring in a middle-aged lady a few months after the removal of a thyroid tumor. Her attacks of dyspnœa became so frequent and alarming that intubation was performed. It gave relief, but she objected so much

to the loss of voice that she insisted upon tracheotomy being performed. This was done, and she is still wearing the tracheotomy tube.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, February 24, 1898.

EDWIN B. CRAGIN, M.D., CHAIRMAN.

Blood Casts of the Uterus.—DR. EDWARD W. PEET presented casts from the cavity of the uterus. They had been passed by a woman who was suffering from purpura hæmorrhagica. Minute examination had failed to show anything but organized blood clot. The patient was a single woman, thirty-six years of age, who had been anæmic for a considerable time. After a sojourn at the Sulphur Springs, she developed purpura hæmorrhagica. She was treated for this first with iron and arsenic, and afterward with ergot and iron. The purpura slowly disappeared. After a month or two she had a very severe attack of herpes zoster. After about two months the purpura hæmorrhagica returned in a more severe form than before. When he had first seen her, last December, she was in bad condition. She was put on red bone marrow on December 16th. On December 25th menstruation came on, and after a good deal of pain she passed these casts. Under the treatment mentioned the number of red blood cells increased very markedly. During the menstrual period the white corpuscles increased to nearly double their former number. It was peculiar that these clots should have retained their shape after passing through the cervix, and that they should have been passed joined together in a chain.

DR. ROBERT A. MURRAY said that he was of the opinion that if the cervix was in normal condition the blood would not be passed in the form of clots from the uterus, although it might be discharged into the vagina and there become coagulated. It seemed to him inconceivable that these casts should have been passed in this form from a virgin uterus. It was true that one of the clots seemed to represent the shape of the uterus, but he had seen similarly shaped blood clots discharged and had been able to prove, by actual inspection, that they came from the vagina.

DR. MALCOLM MCLEAN said that the fact that various-sized clots, both small and large, had been passed would indicate that the uterus had been slowly dilated. This would explain the passage of a large clot. He had seen this even in a virgin uterus, and it seemed particularly apt to occur in anæmic women.

THE CHAIRMAN said that when, as in this case, the discharge of the clot immediately followed severe cramp-like pain, it was reasonable to suppose that the clot had been discharged from the uterus.

A Follicular Cystoma.—DR. A. H. GOELET presented a tumor that he had removed by laparotomy from a woman, seventy-four years of age, on January 26th. According to the pathologist, it was a follicular cystoma. Her physician had been consulted for the first time by her for this condition last October. There was some bearing-down pain at the time, and there appeared to be a large mass in Douglas' cul-de-sac. When he had seen the patient in January, the tumor was of the size of a fœtal head, and it had interfered seriously with the functions of the bladder and rectum. When the abdomen was opened the tumor appeared like an ovarian cyst, but its contents were found by tapping to consist simply of gelatinous fluid. It was removed with comparative ease, and the patient almost completely recovered.

Submucous Fibroid Undergoing Degeneration.—Dr. Goelet also presented a degenerating submucous fibroid, removed from an unmarried lady, twenty-nine years of age. She had not menstruated for a year previously. Instead of menstruation there had been a profuse and persistent hydrorrhœa. She had not been treated by electricity. When the abdomen was opened the uterus appeared like one in the eighth month of pregnancy. The tumor was found to have undergone considerable degeneration, and so it was decided to be safer to remove the uterus, a supravaginal amputation being done. The right ovary was allowed to remain, with a view to diminishing the subsequent nervous symptoms. Recovery had been uninterrupted, and she was now in perfect health. The nature of the degenerative process had not yet been determined.

An Unusual Case of Dystocia with Hour-Glass Contraction in the Second Stage.—DR. MALCOLM MCLEAN reported such a case. The patient, a woman, twenty-six years of age, had gone through her first pregnancy in February, 1896, without untoward incident until the last month, when she had developed considerable œdema associated with albuminuria. She had accumulated forty pounds of flesh during her pregnancy, and she weighed at term one hundred and eighty pounds. She was exceedingly nervous at the time of confinement, and the pains were short and ineffectual. After a number of hours had passed without progress, her physician had performed version and brought down the feet. The delivery of the body was effected with unusual difficulty, and the head at first resisted all efforts at extraction. Suddenly it separated from the body and remained above the pelvic brim. When Dr. McLean saw the case, about two hours later, there were much swelling and contusion of the maternal parts. After some difficulty he succeeded in delivering the severed head with axis-traction forceps. The placenta was easily expressed, and the patient recovered promptly under hot-water douches. Her physician said that on attempting to turn the child he had met with great resistance, which seemed to be due to spasmodic contraction. Subsequent examination of the pelvis by Dr. McLean showed no contraction of any of the pelvic diameters. Her physician having died before the next pregnancy, he had assumed charge. When seen by him in her second confinement, she was in good physical condition. The first stage was slow. The second stage came in with severe pains and the patient became nervous, and but little progress was made. The head was floating above the brim in the L.O.A. position. During the pains the head was only pressed down against the brim, but did not engage. The waters had begun to escape quite early in the labor. At 10 A.M. on December 25th, after having been in the second stage for six hours, the patient was utterly demoralized. He had felt so satisfied that the head could be made to engage easily that he had elected the forceps in preference to version, but to his great disgust and chagrin he found that the head could not be brought down further than the superior strait. An examination with the whole hand failed to detect any irregularity in the pelvis or any abnormality of the child, but the neck of the child was tightly grasped by a true hour-glass contraction of the uterus. It was necessary to force the head up through the ring above before version could be performed and delivery effected. The child was delivered in a moribund condition and died within half an hour, apparently from the pressure produced by the forceps on the head. The speaker said that he had never before heard of a distinct hour-glass contraction in the second stage. No measurements had been made of the child's head, but the baby was well formed and weighed eight and one-quarter pounds.

DR. PAUL F. MUNDÉ said that many years ago he had seen four such cases, but had never reported them. In 1881 he had been hurriedly called by Dr. James W. McLane to assist in the delivery of a woman who

had had a number of children. Examination showed this hour-glass contraction. After working ineffectually for three hours, he had been compelled to perforate and deliver the child, which had long been dead. Although the woman had been under chloroform for six hours or more, she had made a good recovery. This form of contraction did not seem to relax at all under chloroform.

Dr. S. Marx said that, in spite of the theory advanced by the preceding speakers regarding the cause of the dystocia in the case presented, it was inconceivable to him how such a contraction could come on at this stage of labor and prevent its further progress. The history showed a very severe dystocia in the first confinement, and that the head had not engaged in the superior strait. This, as was well known, indicated a disproportion between the fœtal and maternal measurements. He felt sure that in this case the cause of the dystocia was to be found in the relative disproportion of the fœtal and maternal measurements, together with the spastic condition resulting from long and difficult labor. The lesson to be learned was that when the pelvis was rather small and the child rather large labor should not be allowed to continue very long without interference.

Dr. Ervin A. Tucker agreed with the last speaker that the prolonged labor and tired-out uterus were responsible for the spastic condition. In a case of this kind that he had seen, in which version could not be performed at first because of the contracted ring, he had pushed the chloroform to the full surgical degree, and then the ring had relaxed and version had become possible. It did not seem to him wise to leave a woman to suffer in the second stage of labor for five or six hours; it was two or three times longer than seemed to him desirable.

Dr. R. A. Murray said that the tired-out uterus did not require even profound chloroform narcosis to relax it, but it was not so with a uterus which had become tonically contracted. In the latter class of cases it was not the head, as a rule, that presented the obstacle to delivery, but the shoulders. If the head was the cause of the obstruction, it was evidence that the head was relatively too large for the pelvis. The crushing of the head would not be found sufficient to allow of delivery or inarily; it would be necessary also to crush the chest. For these reasons he did not quite understand how Dr. Mundé had succeeded in effecting delivery in the case cited by him. The fact that in that case the crushing of the head had been sufficient showed that the original cause of the dystocia must have been the disproportionate size of the head. In a similar case great dystocia had been met with on two previous occasions, and he proposed in the next confinement, which was expected soon, to place the patient under chloroform at an early stage, and he hoped in this way to be able to deliver her with much less difficulty.

Dr. Mundé insisted that in the case he had referred to there had been no pelvic deformity, the dystocia being entirely dependent upon the contracted condition of the uterus.

Dr. Ralph Waldo remarked that, in his opinion, the discussion had gone rather wide of the mark, as the cases referred to were not counterparts of the unique one reported by Dr. McLean.

Dr. McLean, in closing, said that he was sorry that the theories offered by Dr. Marx did not fit the facts, which had been carefully observed and studied. His case was one in which if the head had been the size of an orange it could never have been brought through, for the very reason that the head was anchored to a neck, and the neck was firmly held by the contracted uterine ring. In answer to the very just criticism that the uterus had become tired out by the patient having been left so long in the second stage, he would say that the reason he had left her so long in this stage without interference was that the head had not engaged, and he had firmly believed that by waiting the woman would quiet down and the pains would then become efficient. The chloroform had been pushed to the full surgical degree, and had been kept at that point for two hours while he had worked most assiduously to effect delivery. The head had not been crowded down into the superior strait, but there was plenty of room, as was readily determined with the hand. By pressure from above, made by an assistant, he had been able to bring the child's head well down into the superior strait with his hand alongside of it; hence there could not have been any obstruction due to a disproportion between the size of the child's head and the maternal parts. He had never yet, in a large obstetric experience, perforated the head of a child in order to deliver it.

Abdominal Hysterectomy for Acute Puerperal Sepsis; Recovery.—Dr. H. N. Vineberg said that in the past few months he had succeeded in saving two lives by hysterectomy for the relief of puerperal sepsis. The previous history of the case about to be reported was quite meagre. The patient had been at first under the care of two midwives, and afterward of a physician, but as she had fever, and developed a series of chills on the nineteenth day, she had been sent to hospital. On admission to St. Mark's Hospital at 11 A.M. she was in bad condition; pulse, 120 and feeble; temperature, 103° F. The abdomen was very much distended and exquisitely tender. There were all the signs and symptoms of severe sepsis, with probable beginning peritonitis. Curettage was performed, and considerable decidual tissue removed. The uterus was then irrigated with an antiseptic solution. Her condition improved temporarily, but the next day she was decidedly worse, so he had decided to perform abdominal hysterectomy and wash out the peritoneal cavity with saline solution. This was done at once, on the twentieth day. She stood the operation well. The following day her temperature was 100° F. and her pulse was very much better. She made a good recovery, and was able to leave the hospital at the end of four weeks. On opening the uterus after its removal, he had found considerable dark débris, with rather a fetid odor, in spite of the fact that intra-uterine douches had been given every four hours, some of them by himself. At the operation the peritoneum presented that opaque greenish appearance which usually pointed to a fatal termination. He had been careful to irrigate the abdominal cavity very thoroughly with saline solution, and had then drained both from above and below. There were no collections of pus in the pelvis. The peritoneum was thickened, and the tubes and ovaries were normal. Of course, the majority of these patients recovered under curettage and intra-uterine douches, but as soon as there was any good reason for believing that the sepsis was extending, he believed the operation of hysterectomy should be performed. The pulse would be found a much better guide than the temperature in deciding upon the degree of sepsis present.

Dr. Paul F. Mundé said that from an examination of the specimen he could not but feel that a uterus looking like that one hardly demanded removal. The success attained by Dr. Vineberg was certainly phenomenal, but it was likely that the result would have been equally satisfactory if the uterus had been left alone and the abdominal cavity had simply been flushed out with saline solution. While he admired the operator's daring and hardihood, and congratulated him on his success, he still felt that the doctrine involved in this case was a dangerous one to be allowed to go abroad. The operator had not given any distinct

indications to justify the operation. If there had been collections of pus in the pelvis, the matter would have been very different.

Dr. Boldt said that he had seen the uteri removed from both of Dr. Vineberg's patients. The first case was one of sepsis due to a portion of retained placenta. If that uterus had been carefully examined, not only with a curette but with the finger—if necessary, by splitting up the cervix—that septic material could have been removed. Personally he had never seen a case of acute puerperal peritonitis cured by operation, although he would not say that such a case had never occurred. In the specimen just presented there was nothing to indicate that the uterus was septic. It was not a case of acute puerperal sepsis, for, if such had been the case, the woman would have been dead before the time mentioned as that at which she had first come under observation. The uterus was quite normal in appearance, he thought, for that period after labor. He fully agreed with Dr. Mundé that the recovery would have been equally assured if the peritoneal cavity had been washed out and the uterus had not been removed. He wished to be courteous, yet he also desired to speak plainly and state his convictions in a spirit of absolute scientific criticism.

Dr. R. Waldo said that he had seen a great many cases of puerperal sepsis, and had yet to see one that he thought would have been benefited by the procedure followed in this instance. It seemed to him that if the uterus had been most thoroughly curetted and irrigated, and then had been left alone, the case would have terminated in the same way. The fact that there were no accumulations of pus in the vicinity of the uterus or in the peritoneal cavity, he thought, justified his speaking against the procedure.

Dr. John Polak said that he had reported to the section last year a case of septic metritis, in which there had been purulent foci in the walls of the uterus but no involvement of the tubes or ovaries or broad ligament. He had removed the uterus through the vagina with the aid of clamps, and the patient had made a good recovery.

Dr. Vineberg said that the criticisms offered did not surprise him. If sepsis evidently came from the interior of the uterus, of course the treatment should be curettage and irrigation of the uterus; but if, in spite of this treatment, the patient's condition became worse and there were evidences of peritonitis, it seemed to him that there was everything to gain and nothing to lose by operating. In these cases the gross source of infection must be removed before a cure could be effected. Regarding the first case that he had previously reported, he would say that if the uterus had been carefully examined after operation it would have been found that the cervix was closed so that it would have been impossible to introduce the finger or the curette. The placental tissue, moreover, was firmly organized, and it was difficult to remove it even after the uterus had been cut open. He was willing to present the specimen from the first case at any time. He would rather perform hysterectomy than split the uterus and insert the finger, as suggested by Dr. Boldt.

Dr. Boldt said that invariably in these cases he split the cervix bilaterally, so that the finger could be introduced and a thorough digital exploration made.

Pregnancy in Women with Uterus Duplex, with Report of a Case.—Dr. Sara Welt-Kakels read a paper with this title. She said that the uterus duplex was undoubtedly of much more frequent occurrence than the literature would seem to indicate. After a critical review of the literature, the following case, occurring in her own practice, was reported:

Mrs. D. S——, thirty years of age, first came under her observation more than five years ago, with a negative family history. Her menstruation was regular and the flow normal, but she was anæmic and suffered from dysmenorrhœa. The thoracic organs were normal, as were also the external pelvic diameters. Bimanual examination showed a small vaginal introitus and a lacerated hymen, and a small uterus acutely anteflexed, with the fundus pointing to the left. A second examination revealed another and somewhat smaller introitus, and another lacerated hymen. The uterus was smaller than on the other side, and had very thin walls. The fornices of both vaginæ were flattened near the septum. The right uterus measured one and one-half inches, and the left two inches in length. The adnexa could be easily palpated on each side, and the space between the two uteri could be felt on bimanual palpation, a sound having been previously introduced into each uterus. The distance between the two vaginæ was about one inch. During the next menstrual period, the speaker said, she had had an opportunity of observing both uteri menstruating simultaneously. This had occurred in the majority of cases on record, although a case had been reported in which the two uteri menstruated at different times, and another in which the two uteri menstruated alternately at an interval of one month. In the present case the cervical canal was dilated, and efforts were made to strengthen the weakened uterine muscle. An intra-uterine stem was inserted, and by this means the dysmenorrhœa of which the patient complained was somewhat abated. She wore this stem for a number of months. Subsequently, after eleven years of married life, she became pregnant in the left uterus, and then the menses ceased on both sides. Only a slight degree of hypertrophy was observed in the right uterus. The woman was taken in labor unexpectedly, and delivered during the speaker's temporary absence. The child presented by the breech. The placenta was delivered spontaneously. On account of the speaker's absence she was unable to state whether or not the empty uterus participated in the contractions, or whether a decidua had been discharged from the unimpregnated uterus. After this confinement the patient passed from observation, but was located again a short time ago. It was not claimed that the treatment had been the direct cause of the patient becoming pregnant, though it quite possibly contributed to this result. According to the recorded cases, pregnancy not infrequently occurred. In some, only one uterus seemed to have become pregnant; in others, the uteri alternated; occasionally pregnancy occurred simultaneously in both uteri. There also seemed to be a tendency to inertia of the uterus during parturition. The septum was often torn completely by the descending part. This occurred in the case just reported. The prognosis for the child was very good.

Dr. Mundé said that four or five years ago he had reported about seven cases of congenital malformation of the female genital organs, two of which were of the kind described in this paper. In his own experience he recollected only one case of pregnancy in a uterus duplex. It was true, as had been stated, that the diagnosis was easy—that is, if one happened to think of such a condition; but it was very much like the many cases of ruptured tubal pregnancy, that were overlooked not many years ago. In the case of pregnancy in a uterus duplex that had come under his observation, he had found a tumor projecting from the right side of the uterus, in a woman giving the usual signs and symptoms of pregnancy. On opening the abdomen, he had at first supposed that he had to deal with an interstitial pregnancy. The aspirator withdrew some liquor amnii. Previous to the operation a sound had been passed up three inches toward the left. During the operation he had asked an assistant to insert the sound, and at first it went again up three inches to the left, but on changing the position of the

sound slightly it had passed in up to the very top of the tumor. The diagnosis having been made clear, the abdomen was closed up. The patient aborted that night, and made a good recovery. The woman had had a child before this on the left side, and that cervix had been lacerated. It was this that had led him astray. Among the strange cases of this kind reported was one in which a woman had gonorrhœa on one side only.

Dr. Joseph Brettauer said he agreed with the reader of the paper in calling her case one of uterus duplex. He referred to a case of uterus bicornis subseptus. He had felt at first two distinct uterine cavities and a double vagina. The latter he had excised. He had not seen the woman again for a long time, and had then been surprised to find that she had been pregnant and had aborted at the fourth month. On again examining her, he had found that the septum had disappeared from the uterine cavity, although there was still a septum in the cervix.

Dr. Vineberg said that he had had a woman under observation for years, whom he had at first curetted for an abortion in the right uterus, not noticing at the time the true condition. At a subsequent examination, finding a virgin os, he had made a further investigation. In another pregnancy the child had been expelled through the septum, so that now the patient presented the appearance of having three ora uteri.

Dr. Ladinski said he had seen recently two cases which appeared to be examples of double uterus and double vagina, although he had not had an opportunity of examining them under narcosis. In the second case the uterus on the left side was gravid.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 21, 1898.

George Tucker Harrison, M.D., President.

Address of the Retiring President.—Dr. J. E. Janvrin delivered this address. After speaking of the large share of credit due the association for its crusade against the abuse of medical charity, he touched upon the desirability for greater unity in the medical profession in this county and State. In this connection he said:

"In a recent conversation with Surgeon-General Sternberg, the president of the American Medical Association, he expressed to me his very strong desire that in some way, not derogatory to the dignity of the American Medical Association, or contrary to its code, the New York State Medical Association and the New York State Medical Society, and together with them the two county organizations, might so arrange affairs as to bring the whole regular medical profession of this State into harmony with the American Medical Association.

"I am fully in accord with the sentiments expressed by Dr. Sternberg, and, in fact, I might here say that this idea is not a new one to me. It has had my serious thought for years, and it seems to me that this organization should also take it into serious consideration. For several years neither the State nor the county societies have had a code of ethics. Whether they can again be induced to adopt the code of the American Medical Association is a question; but of this fact I feel perfectly confident, that quite a large percentage of the members—especially the younger members of the Medical Society of the County of New York—are well disposed to take the matter into consideration. By making this statement it has occurred to me that possibly some movement might be made in this association whereby our two county organizations might confer, by duly appointed committees, and the result be that the old feuds will cease to exist and all members of the regular profession in our county—and then later in the State—be again brought into harmony among themselves and also with the American Medical Association. I make this simply as a suggestion to the incoming officers, and through them to the association itself."

Address by the President-Elect.—Dr. George Tucker Harrison, in delivering this address, took the opportunity briefly to sketch the history of the progress made in medicine during the century now drawing to a close. He thought that modern medicine might be said to date back to the anatomical and physiological researches of M. F. Bishop, Cuvier, and other brilliant followers of the French school in the early part of the century. After dwelling upon the part played by England in the evolution of modern medicine and by our own country, Dr. Harrison delivered a glowing eulogy on the personal character and brilliant professional labors of the renowned Dr. J. Marion Sims.

Methods of Administering Antitoxin.—Dr. Louis Fischer said that although the usual method of administering diphtheria antitoxin had been subcutaneously, he had within the last three years seen at least fifteen or twenty cases of diphtheria, of a very mild form, treated by giving the antitoxin per rectum. He had also tried giving it by the mouth. Last month he had had an opportunity of experimenting in this direction in a certain house in which there were seventeen cases of true diphtheria. More than twice that number of people had been exposed to the disease. After the rectum of each patient had been washed out with soap and water, each of the seventeen received from fifteen hundred to two thousand units of antitoxin per rectum. Not a single one of these cases seemed to show any benefit from this treatment. But of the people in this house in whom he had endeavored to produce immunization by giving the antitoxin by the mouth not one contracted the disease. The dose given by the mouth and by the rectum was the same as that used for subcutaneous injection.

Report of the Committee on Hospitals.—Dr. George D. McGauran presented the report of this committee. He said that it was gratifying to note the greater courtesy with which the representatives of the medical profession were received by the new commissioner of charities. A memorial had been drawn up and presented to the charities commission asking that the medical profession in general be given a larger representation in hospitals than heretofore. Referring to the controversy at Albany over the "dispensary bill," he characterized the arguments used by the opponents of the measure as deliberately insulting to the medical profession. The chief arguments presented in favor of the passage of the bill were (1) the tendency of unrestricted charity as observed at the dispensaries to pauperization of the community, and (2) the fact that the physicians were compelled as taxpayers to pay twice—paying taxes and, in addition, giving their services to these institutions.

Result of a Dispensary Investigation.—Dr. Wickes Washburn read the following letter which he had just received, and which contained the result of an investigation made by the Charity Organization Society. "The following tabulation shows the result of an investigation of the patients treated at the —— Institution between January 22d and February 11th—that is, all the patients who reside in the borough of Manhattan. The number able to pay was 106; the number able to pay something was 39; not found or false addresses, 131; unable to pay, 231; removed, refused information, etc., 13; total, 520." Dr. Washburn remarked

that the figures indicated that in this particular series about fifty-five per cent. were able to pay.

The Opinion of a Dispensary Manager.—Dr. Frederick Holme Wiggin then read a letter which he had received from a former manager of one of our large dispensaries. This gentleman, speaking of that institution, said: "In my opinion it is of great service to the ginmills of the region. The whole system is an utter scandal. Physicians give almost half of their time to free practice, and they may be safely trusted to attend to the ordinary needy patients."

Formal Indorsement of the Dispensary Bill.—On motion of Dr. A. W. Warden, the following resolution was unanimously adopted:

"*Resolved*, That it is the sense of this association that the 'dispensary bill' be indorsed, and that a copy of this resolution be sent to the chairmen of the committees on public health of the senate and of the assembly."

To Extend the Olive Branch to the County Medical Society.—Dr. T. H. Manley, acting upon the suggestion made by the retiring president, Dr. Janvrin, in his address, moved that a committee of seven be appointed by the president to confer with the County Medical Society, with a view to sending a delegation to the American Medical Association at its coming meeting in Denver; and that the secretary be requested to transmit to said County Society a copy of that part of Dr. Janvrin's address bearing on this topic.

Dr. Janvrin, in explanation of the proposed action, said that very many of the members of the County Medical Society were also members of the County Medical Association. There were a great many young men in the County Society who knew nothing about the troubles that existed fifteen years ago, yet they were loyal to what might be called the unwritten code of the American Medical Association. They would gladly act as delegates from the County Society to the meetings of the American Medical Association. For a number of years the County Society had had no code whatever; it had given up the new code. He believed if the association would simply take the initiative, a feeling would be engendered in that society which would cause it to come back and become a part of the American Medical Association. He based that opinion upon the fact that he knew that some of the officers of that society were strongly in favor of such a movement. The association would lose none of its dignity by offering the olive branch. If those who were members of both county organizations were sent as delegates to the Denver meeting this year, it was not improbable that at no distant date the troubles that had existed in the past would be obliterated, and the profession in this county would be once more united and strong. The proposed committee was one of conference only, and it bound the association to nothing.

Dr. Manley remarked that the work of the committees in regard to the dispensary bill had done much to weld together the two organizations.

Dr. George D. McGauran remarked that one of the commissioners of charity had told him that the medical profession here could hardly hope to gain much as long as it was divided into factions and maintained two separate county organizations.

After some further discussion, participated in by those who opposed as well as by those who favored the proposed movement, Dr. Manley's motion prevailed.

Scenery en Route to Denver.—Dr. A. E. Gallant announced that at the next meeting of the association, March 21st, he intended to entertain the members and at the same time awaken more enthusiasm in the coming meeting of the American Medical Association in Denver, by giving a stereopticon exhibition illustrating some of the beauties of the trip.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENTARY—LATENT OR EPHEMERAL PERICARDIAL EFFUSIONS—A SMALL-POX EPIDEMIC—THE QUEEN VISITS NETLEY HOSPITAL—INFLUENZA—GLASGOW UNIVERSITY—LONDON HOSPITAL—DEATHS OF DRS. REMFRY, JOHNSTON, M'FALL, FULLER.

London, February 18, 1898.

The parliamentary session is not to be without interest to the profession. The Queen's speech promised amendment to the vaccination laws. One change in this respect will be the use of glycerinated calf lymph at the option of the parent. It is hoped this may propitiate the faddists.

Much more important in some respects is the proposal to substitute domiciliary operations for the vaccination stations. If this should be done, it will be a far-reaching change and throw much of the work on the general practitioners which has been done by the public vaccinators.

The midwives bill is likely to be again brought forward. Its advocates have secured a place for its second reading on May 11th. Unless the government, therefore, should by then be compelled to take all the time of the house for imperial affairs, it may possibly come to a division. The profession must again be up and doing, or they may wake to find a set of inferior practitioners established and so much of their occupation gone. It is useless to go over the whole ground now, but the danger is as great as on the last occasion.

Every indication has been given that the London University question will be attacked, but how far the government is prepared to insist on passing a bill is by no means clear. If seriously opposed it will probably drop it.

Yesterday the government admitted in the house that the dearth of candidates for the army medical service continues, and stated that the steps intended to be taken will shortly be announced.

Dr. Ewart has brought before the Clinical Society the subject of latent pericardial effusion, which he has found to be more frequent than is generally supposed. Walshe, indeed, mentions it, but scarcely any other author. The dulness to which it gives rise is often attributed to cardiac dilatation, from which it differs in outline. It also gives rise to the characteristic dull patch in the back. The short duration and moderate extent of these minor effusions were also considered, and other points of the paper were the absence of the pain of pericarditis or of the pressure symptoms of large effusions, the obscurity of the pathological etiology, and the desirability of early recognition; since in many cases it may appear that these slight and often ephemeral effusions may turn out to be the early stage of more dangerous large effusions.

In the conversation which followed the paper it was mentioned that though effusion is often found at the post-mortem when it had been unsuspected during life, it is also true that when diagnosed during life it is frequently not found post mortem.

In reply to questions Dr. Ewart said that the patch of dulness at the angle of the left scapula in pneumonia arose from compression of the descending bronchus, giving rise to the rhonchus. The posterior cardiac dulness extended to the spine. Of course emphysema would interfere with the mapping out of the dulness. The site at which effusion could be earliest detected he found was a triangular patch in the fifth right interspace just to the right of the sternum, and good reso-

nance in this position would exclude pericardial effusion. There was a similar patch just below the left nipple, but on this spot stomach resonance often interfered with accurate percussion. No friction had been detected in any of the cases, although the post-mortem showed that fibrinous exudation had been present. The distinguishing mark is the shape of the right border, which is convex in cardiac enlargement, while in effusion it presents a straight line, making a sharp angle with a horizontal line at the right nipple. Dulness often extends beyond the apex.

Small-pox has been prevailing for several weeks in Middlesborough, a Yorkshire town of nearly thirty-eight thousand inhabitants. The railway company has suspended excursion traffic to the town, and temporary hospitals are being rapidly put up to meet the emergency. Dr. Reece, government inspector, went down on the 10th, when two hundred and thirty-six cases had been reported. The number has now risen to three hundred and sixty-five. The town is frequented by a large number of migratory persons, which greatly adds to the difficulties, but the authorities are active in carrying out precautions. House-to-house visitation is employed with energy, and vaccination and revaccination are being done, not only in Middlesborough but in the outlying district.

The Queen went to Netley Hospital on Friday to see the soldiers invalided from the Indian frontier war. The sick and wounded were in large numbers, but the Queen addressed a few words to each individually and her sympathy is said to have greatly gladdened the sufferers. Her Majesty has since requested photographs of the soldiers to be sent to her, with a statement of the case on the back of each portrait.

Dr. White of the Dareuth Hospital has been cashiered with a quarter's salary, as he declined to resign. It is, as I predicted: a scapegoat is made of the medical officer, and it seems as if those whose conduct ought to be inquired into are not even to be censured.

Influenza persists. There was a drop of four in the deaths last week—scarcely enough to encourage us. The weekly mortality has been 40, 73, 88, 102, and 98. There was a fall in the deaths in the eastern and southern quarters but in the western the rate nearly doubled.

Glasgow University circles are exercised over the vacancy in the professorship of forensic medicine. It is thought an excellent opportunity to set apart the teaching of public health and establish a chair for this great and increasing subject.

The London Hospital College is to be further enlarged. It was rebuilt in 1886–87.

Dr. Renfry, assistant obstetric physician to St. George's Hospital and lecturer on midwifery in the school, died suddenly on the 11th inst. He was only thirty-seven years of age, and what he had already done gave promise of greater success. He was on the council of the Obstetrical Society, and contributed to the transactions as well as to the journals.

The following deaths are announced: Inspector-General Johnston, M.D., on the 11th inst., aged eighty-four years. He took his M.D. in 1835 and joined the army medical service in 1838. He retired in 1863.

Brigade Surgeon Lieutenant-Colonel D. C. McFall (the husband of Sarah Grand, the novelist). He served in the Crimea and the Indian mutiny, and received medals for each. He did much service in cholera epidemics during his twenty years in India.

Surgeon-General S. Fuller, who also served through the mutiny and subsequently in Egypt.

Cycling is Injurious to health from three causes—the contraction of the muscular system, chills following perspiration, and the stooping-posture, which renders respiratory movements defective.—MENNELLA.

GUINEA-PIGS FOR TEST INOCULATIONS IN RABIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An article in the MEDICAL RECORD for February 19th, by Dr. N. G. Keirle, of Baltimore, has interested me very much. For nearly a year Dr. R. J. Wilson and I have been carrying on experimental investigations in rabies at the Research Laboratory of the New York health department.

We have found that guinea-pigs are better adapted than rabbits for inoculations done to demonstrate the absence or presence of rabies in suspected cases sent to us for that purpose. Guinea-pigs are much more susceptible to the virus of rabies and are less liable to die from other causes, the possibility of which attend all subdural inoculations. Guinea-pigs also develop the disease in many cases much sooner than rabbits, their incubation period being always shorter when inoculated subdurally and frequently less than half as long. As Dr. Keirle does not refer to these points in his paper and apparently has used rabbits almost exclusively, I think it will not be amiss to demonstrate my point by referring to two cases in which guinea-pigs have been the better animals for these tests. During the last three weeks four fatal cases suspected of having been rabies, two in human beings and two in dogs, have been referred to the laboratory of the health department for investigation.

The first case I shall refer to, and which will be given in detail later, was that of a man who died of what was supposed by the clinical history to be rabies. Part of the brain removed at the autopsy was sent to the laboratory and from a portion of this material two guinea-pigs and two rabbits were inoculated subdurally. On the fifth day after inoculation furious rabies developed in one of the guinea-pigs and death followed on the seventh day. The other guinea-pig developed the disease one day later, that is, on the sixth day, and died on the eighth day. The rabbits showed no evidence of the disease until the sixteenth day, when they developed the paralytic form. In case a patient were to be treated after being bitten by a person or animal suspected of having rabies, this difference between the incubation periods of guinea-pigs and rabbits would be of the greatest value. Treatment very seldom begins before the third day after the bite, and frequently not until the fifth day, owing to many reasons. Therefore it seems to me best, immediately when possible, to perform autopsy on the suspected animal and inoculate guinea-pigs subdurally. If on the sixth or seventh day the animals do not show symptoms of rabies, treatment will be unnecessary, or, if begun, should be discontinued before virulent cords are used for the injections.

In the second case, in which guinea-pigs proved to be very valuable, rabbits were inoculated by two different sets of investigators, and all died of septic infection from accidental contamination, while the guinea-pigs used by the bacteriologists of the health department lived and are now under observation. The inoculations were made from the brain of a woman supposed to have died of rabies. This difference in the susceptibility of rabbits and guinea-pigs has often been observed by me. Guinea-pigs rarely die from accidental contamination, while rabbits not infrequently do, and generally within twenty-four hours, cultures from the various organs in these cases always growing in different media. The micro-organism is usually a short bacillus.

Therefore as these two examples cited above have been confirmed many times by similar demonstrations, they seem to me of sufficient importance to be taken into account.

I think all such work as Dr. Keirle has done and is

doing is of great value, if it will help eventually to clear up much of the mystery and superstition surrounding such a terrible and fatal disease as rabies.

FOLLEN CABOT, M.D.

128 EAST THIRTY-EIGHTH STREET, NEW YORK,
February 13, 1898.

THE DIFFERENT FIELDS OF OPERATIVE SURGERY AND GYNÆCOLOGY IN EUROPE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: When one has been for twoscore years a general practitioner of medicine in America and then for the first time visits the large hospitals of Europe, his observations ought to be of sufficient interest to be recorded and the record made accessible to such of his countrymen as are alert and up to date in their profession.

Believing that the MEDICAL RECORD will reach practitioners of this class in greater number than any other publication, I desire to contribute to it such of my experiences as in my judgment will interest the general practitioner. Personally my predilection is gynæcology, my work having latterly been chiefly in that line, though I must necessarily have an intimate acquaintance with its near cousin—surgery—and therefore the title above. As the title implies, the fields are "different," and an intelligent account is not always easy without some account of the differences in the places and habits of the peoples. No history of a country or city is intended to be given further than the account may serve the main narrative of these papers. It is not meant that any city, clinic, or operator shall be advertised, but the character of a clinic or man when extraordinary will often be referred to, as well as the size and character of the city in which it or he is to be found. Furthermore, there is no intent to produce a guide for the medical pilgrim, as it is not probable that many who read these papers will travel the route described. A daily memorandum was made of my observations and from these I chronicle the following:

Early in September, 1897, I left Washington, D. C., and in five hours was in New York City, where I spent eight weeks in the medical hospitals and clinics of that live city before taking the *Fürst Bismarck* for Hamburg. Next to London, Liverpool, and New York, Hamburg is the most important commercial place in the world. It has about six hundred and twenty-five thousand inhabitants, but no university and no medical college. At Eppendorf, however, formerly a suburban town but now a part of Hamburg, is one of the best-appointed hospitals of Europe. It would be more correct to say collection of hospitals, for eighty separate buildings are already completed and ten more will be built. These buildings are scattered over what appears like a large farm containing a village. There are fifty-five hectometres of land and the inhabitants number about three thousand. Architects, carpenters, gardeners, and various artisans live and labor here. Of the medical corps seven are directors and operators-in-chief of separate departments, twenty-six are assistants, and more than two hundred are nurses. The pavilions and operating-rooms have every modern improvement and are lighted by both gas and electricity. The bedsteads are of iron, painted white or enamelled, and supplied with wire springs. There are more than eighteen hundred beds in the pavilions. Adjoining these pavilions are rooms or spaces for amusements, separate and with appropriate supplies, and convalescents pass time enjoyably here. The floor is of stone and the walls are enamelled. Baths adjoin the pavilions, but one building contains only baths of every kind and of the best quality. Dry-air baths are given in a series of adjoining rooms, and in passing from one to another a patient finds the temperature successively elevated until profuse sweat is produced. Steam or vapor baths have the same arrangement of rooms. There are also shower baths and electric baths, and what was to me of greater interest was to find patients living in tubs. These tubs are very large and are covered with canvas. Patients eat and sleep in these tubs, the entire body being submerged; for many months only the head is kept above water. I saw one woman who had been in her tub for eleven months continuously on account of bedsores on her back. Another woman, with tuberculous disease of the skin and joints, had lived in one for six months. I found her drinking wine and very happy. One building is called the "deadhouse" and is under control of Prosector Franklin. This building again is a model of its kind. There are a number of tables, all of stone, over which there is a skylight affording the best of light for autopsies. The daily average is four autopsies in this room. When done with the body is laid into what appears like a fuel box at one end of the room: the lid is put over the body, and by a spring attachment worked from outside of the box the body is dropped over a slide into the basement. There are adjoining rooms for histological and bacteriological work in laboratories with all modern appliances, instruments, and chemicals for the fullest scientific research. There are separate buildings for infectious diseases—one for small-pox, one for scarlet fever, and another for diphtheria. For these infectious patients there is a special department in the laundry, where their clothing is subjected to high heat for a long time. The laundry is an immense affair, and likewise another building which is devoted to culinary work. There is also a separate building for delirious patients. Near the entrance of the grounds there is a building for operating-rooms, of which there are three, one for men, another for women, and a third for abdominal and pelvic operations. Dr. Kümmel does general surgery, but is a well-known gynæcologist, and is easily the greatest figure among the operators at the Allgemeine Krankenhaus at Eppendorf. He has seven pavilions, averaging thirty patients each. In one of the laboratories he has an apparatus and operator under his control for Roentgen-ray photography. The work done is remarkably fine. Dr. Sick has rank and authority equal with Kümmel, and operates daily at the Neues allgemeine Krankenhaus. Dr. Graff has rooms of his own and pavilions under his control. He is not assistant to anybody, but has rank second to Kümmel and Sick. The assistants are graduates in medicine from German universities and receive their appointments for terms of two years. When an assistant proves satisfactory the first term, he is given the preference if he desires to be his own successor; but he is not promoted in rank nor is his remuneration greater than during the first term. He is furnished with a comfortable room, bed, and washing. The assistants all dine together, and are given very good board with coffee, beer, or wine, as they may prefer, and are paid besides 100 marks a month. Dr. Kümmel is paid 6,000 marks per annum and has meals when he desires. He is permitted to practise in the city all unoccupied time. About ten thousand patients are treated annually at a cost of about 1,500,000 marks—an average of something like 75 cents a day. Cost of ground, 788,850 marks; houses, 5,195,300 marks; furniture, 1,137,200 marks; total, 6,32,500 marks; $100 is precisely 412½ marks.

Dr. Prochownick has a private clinic on his own property, centrally located among the wealthy residents of the better part of the city, on the Alster. It is a large three-story building, with twenty-four beds, eight being first, eight second, and eight third class. Third-class patients pay nothing, but the city pays

him 1½ marks a day for keeping each patient and nothing for operation. It is less than the cost of keeping a patient, but Prochownick has these beds constantly full. Patients of the second class pay for room and board, but nothing for operation, and only those of the first class pay for operation. He comes to his hospital only at fixed hours, having office hours elsewhere as well as visiting-hours for other patients. He has two assistants and two voluntaries, who help him at the hospital and do very good work in his laboratory in pathology and bacteriology. They also assist at operations and look after patients in the hospital. Prochownick is not only a very clever operator but he is also very ingenious in mechanics, as is manifest in everything connected with his operations. Cold, warm, or lukewarm water is turned on and off for washing hands, and wash bowls are emptied without touching anything with the hands—all by pedals worked with the feet. Tin cans containing sterilized gauze have the lids lifted by the same method. His operating-table is remarkably ingenious for variety of position.

Travelling from Hamburg one hundred and seventy-eight miles to the southeast, I am in the capital of Germany, which next to London and Paris is the largest city of Europe. It is situated on the navigable Spree and is the greatest manufacturing city of continental Europe. Within the last three-quarters of a century perhaps no city in the world has exceeded it in rapidity of substantial growth, it having increased from about two hundred thousand in 1820 to nearly two million inhabitants to-day. It has a garrison of twenty thousand soldiers. It has a university with more than five thousand students, besides medical students and graduates, of which there are nearly three thousand additional in and out of the university, but all of whom seek the laboratories and clinics with the great wealth of material which Berlin affords.

Much was said to me in New York regarding a recent law or regulation which prohibits Americans from attending German clinics, and therefore I made numerous inquiries regarding this, interrogating even medical teachers and professors connected with the university. The answer always came that no such thing existed. Students, however, told me, always Americans, that no Americans were taken as assistants at the königliche clinics, which clinics are always under what are known as "Hofärzte" (official doctors). The clinics of Olshausen and Bergmann are of this class, and I attended both, the latter oftener than any clinic at Berlin. The amphitheatre has a capacity for about two hundred students, and I believe fifty Americans come daily to this overcrowded clinic. I found no Americans among the assistants, but Bergmann was very cordial and in everything most courteous toward me. From three hundred to five hundred Americans, it is said, attend the clinics of Berlin yearly. The university is supported by the government of Prussia, and the königliche clinics of Bergmann and Olshausen are supported by the same authorities. If an American State supported a clinic, would not the assistants be not only American but also of the particular State which paid for that clinic? That there is a prejudice in Berlin against Americans there is no doubt, but it exists more among the students than among the professors.

Bergmann's clinic is on Ziegler Strasse, and adjoining it is the Poliklinik. Dr. Nasa is Bergmann's first assistant and is director of the Poliklinik. Including ambulant patients, the Poliklinik has more than twenty thousand patients yearly. Of these the more difficult in general surgery are turned over to Bergmann's department, in which perhaps three thousand patients are treated annually. Bergmann is surgeon to His Royal Highness the Kaiser, and is known to the world from his service to the father of the present emperor and his differences with a distinguished English consultant. Altogether Bergmann is freer with the use of the knife than any other surgeon I have seen. American students say, "He is a peach when it comes to operating." There is no tissue that a knife can cut, from throat to rectum, which his knife refuses, and I have not seen the disease so far advanced that Bergmann will not operate for. He is perhaps past sixty-five years old and of very fine presence—with full beard and long hair on the head, nearly six feet high, and perhaps two hundred and twenty pounds in weight. He is discourseful as a lecturer but quite a "spellbinder." His only anæsthetic is chloroform. He washes with ordinary soap and water, then alcohol, and lastly sublimate solution, often omitting alcohol. The sterilized gauze is handed from a tin sterilizer with the gloved hands of a nurse, who wears long white cotton gloves, of course sterilized.

In Bergmann's wards there are three classes of patients: First-class pay 9 marks a day, second-class 6 marks a day, and third-class 2½ marks a day when paid by the individual and 2 marks when paid by the Workmen's Endowment or Insurance Association. All workmen in Berlin, at least all artisans, are compelled to belong to such an insurance company and pay in weekly a small sum which secures them comfort when sick. The Königliche Frauenklinik, also on Ziegler Strasse, not far from Bergmann's, is under the direction of Olshausen, who lives within the building. He or his assistants begin operating at 7 A.M. when they have material, and Olshausen gives a public clinic at 10–11 A.M., both obstetrical and gynæcological, as both departments are within the same building and under his control.

Berlin is a city of private clinics for women's diseases. These are often fine properties, built and possessed by the most celebrated gynæcologists, who have great wealth and large incomes from their practice. Of this type are Landow's and Martin's clinics. The former is under the control of the owner and a younger brother. They have an operating-room on the first floor, with an adjoining room for washing the hands and preparing the person of the operator; across the hall is another room for giving the anæsthetic. On the same floor is a very large room, with seats for quite a large class and gynæcological chairs and appliances. Here examinations and diagnoses are made, tampons and pessaries applied, and trivial operations sometimes done. The Landow brothers are most thoroughly cosmopolitan, having under their instruction physicians and gynæcologists from all parts of the world, who come here to be benefited by this clinic. I find two Americans among the assistants. The younger Landow speaks English fluently and is conversant with American peculiarities and wit. He quotes Mark Twain on the German language with freedom and zest. They operate by no German or French school, and appear to be totally void of all national prejudice. The first assistant, Dr. Pick, is perhaps the speediest pathologist in Germany. While the pelvis was open and Landow in doubt as to the extent the adnexa should be removed, fearing carcinoma, I saw Pick freeze, cut, stain, and examine under the microscope, with negative result, in seven minutes by my watch. There is an extensive laboratory with chemicals and appliances in this private hospital, which I found most interesting. Pathology, bacteriology, and histology are ably taught by Dr. Pick, with their especial relations to gynæcology, and here were Americans galore, among them a woman student from Baltimore. Pick's students attend Landow's operations. Landow's clinic is at No. 21 Phillip Strasse. Martin's clinic is one of the best known in Berlin, and he is perhaps the speediest op-

erator doing laparotomies to-day. I saw him cut through the abdominal wall and remove a cyst containing nearly three gallons of fluid, and in precisely three minutes from the time of the first incision the entire tumor was removed. In twelve minutes more the patient was removed from the operating-table. The patient lies perfectly flat on a Martin table, which permits of no Trendelenburg position. The woman's legs hang down over the end of the table and Martin sits between them, so that his body easily rests against her perineum. He has one assistant only besides a female nurse. The latter hands all instruments.

Mackenrodt has his private clinic at No. 10 Johannes Strasse. He was Martin's assistant for four years, but does not use a Martin table. He likes the Trendelenburg position in laparotomies and operations per vaginam. Mackenrodt is enthusiastic in regard to a method which he is promulgating for cure of cancer of the uterus He removes the uterus and appendages per vaginam without ligating the uterine or ovarian arteries. He does this with a Paquelin cautery and by a method which he is developing for publication. He told me he operates in ninety-two per cent. of all cases of carcinomatous uterus that come to him, while some operators in Berlin operate in only fifteen per cent. of cases presented. By his present method Mackenrodt lost his first seven cases, but since those first cases eighty-eight per cent. of his patients have recovered and regard themselves cured. He has had forty-three cases in which he operated by this method, and for three and one half years he has not used the knife.

I visited Schleich, who has a private clinic in general surgery about two miles from the clinical centre of Berlin. He has rather small but neat rooms up stairs, and is a very cheerful young man, perhaps thirty-five years old, with clean-shaven face, presenting the appearance of a well-kept American priest. His method of infiltration is much practised in America, but here again is a prophet not without honor except in his own country. During the five weeks of daily attendance at surgical clinics at Berlin I saw one Schleich infiltration.

Leipsic is one hundred and one miles south of Berlin, in Saxony, has nearly four hundred thousand inhabitants; it is one of the most important commercial towns of Germany, and the centre of the German book trade. In this historic town Luther had his great career and lives in appropriate monument and statue. Goethe and Mendelssohn had their chief careers here, and Richard Wagner was born here in 1813. A monument also tells us that Hahnemann, the father of homœopathy, died here in 1843. The most prolonged and sanguinary battle on record was fought here, October, 1813, when Napoleon with one hundred and fifty thousand soldiers withstood for four days the allied forces of three hundred thousand troops. Two thousand cannon were brought into the field and one hundred thousand men were lost. And while so rich in historic memory this is also a town of modern culture. The King of Saxony has a palace in Leipsic. The city has a university with three thousand students, nearly five hundred of whom are medical. The restrictions are such that nearly half are prohibited from attending clinics. The first two years medical students are taught anatomy, physiology, chemistry, and the primary branches of medicine only. At the close of this two years' term these students are examined, and if they pass satisfactorily they are then admitted to the study of obstetrics, surgery, practice, etc., and permitted to attend clinics. The königliche clinics here are supported by the university fund, and the university is the affair of the government of Saxony.

Professor Trendelenburg, formerly of Bonn, the inventor of the chair and position now so much used by the gynæcologist, is director of the königliche allgemeine chirurgische Klinik in St. Jacob's Hospital. Three and a half years ago he was called from Bonn to his present position. He has a spacious amphitheatre and operates before a large audience, and also gives clinical lectures here. He keeps a photographic record of his more important cases, and his Roentgen-ray laboratory, like Kümmel's, is within the hospital and under his direction, and is the first I have seen in Europe to equal Kümmel's. I was shown a Trendelenburg chair by the inventor. It is a huge affair and very unlike in appearance any chair I have seen, but it gives the position of Trendelenburg. It cost $250, and would carry a horse as readily as a woman, if appearance goes for anything. Trendelenburg has extensive wards and plenty of material for the very good surgery which he does at his clinic.

The königliche Frauenkrankenhaus, under Professor Zweifel, is quite near St. Jacob's. It is also called Universitäts Frauenklinik, and has, like all these public German clinics, obstetrical and gynæcological wards within the same building and under the same man. Zweifel, like Trendelenburg, has a large amphitheatre, in which he operates and gives clinical lectures. Dr. Menger is Zweifel's first assistant, and in a large room in another part of the building he has four gynæcological tables in separate stalls, where he examines patients and teaches diagnosis and minor treatment of diseases of women He uses Hodge, Thomas, and Hodge-Smith pessaries, and I find him unusually clever in handling patients and making diagnoses. His honeyed words subdue sensitive and refractory females until they tolerate his bimanual manipulation to an extent I never witnessed before, except under influence of an anæsthetic. He introduces the index finger into the vagina and at the same time the middle finger into the rectum, while with the other hand over the abdomen he manipulates so as to make the diagnosis with precision. The finger in the rectum is covered with a very thin finger condom especially made for that purpose. He assures me these condoms are so thin that they in no way interfere with the finger sense. He uses the same condom a great number of times by simply leaving it on the finger. After using it he washes the hand in soap, then in sublimate solution, dries the condom on the finger with a towel the same as the other fingers are dried, and dusts it with rice powder; then he rolls it upon itself as he takes it off his finger, and places it with others in a small tin box, containing more rice powder.

Zweifel is reluctant to cut into pelvic tissue for inflammation or suppuration. Up to 1892 he had operated more than two hundred times for cellulitis and pyosalpinx. To-day less than five per cent. of such patients as were operated upon before 1892 have the knife applied. He uses instead hot douches, tampons, etc., for months if necessary, and finds thus that the use of the knife is seldom required. He says that when one begins to cut into the substance of an ovary or oviduct inflammation or suppuration usually supervenes, making further operation necessary until ovaries or oviducts are all destroyed. New operating-rooms are being built for Zweifel and Trendelenburg which will enable them to have separate rooms for laparotomies alone. Trendelenburg is frank in saying he does not personally deem this necessary and has it done out of deference to public opinion.

Sänger does his work in a large three-story building erected by himself for a private clinic. He eschews all rules—so he said when interrogated as to when he would operate for carcinomatous uterus, as to his preferences for the abdominal or the vaginal route, etc.; but in practice I observe he goes by rules just the same. His operating-table is very ingenious and he

is dexterous in his manipulations and operations. He points to the rubber basin under the hip of his patient, which carries débris into the bucket below by means of a rubber apron, and tells me he used the first one of those ever seen in Europe. It was presented to him by Howard Kelly, of Baltimore.

STREET CLEANING—IS IT THE WEATHER OR THE DIRT?

To the Editor of the Medical Record.

Sir: In your issue of February 26th last you criticise adversely the work of this department, and say that you hope, for the sake of the new street-cleaning commissioner's reputation and peace of mind, that this deterioration will not be progressive, etc.

Had this criticism appeared in one of the daily newspapers, it would simply have been attributed to the political policy of the paper; but in the Medical Record it is presumed that the interest of the city at large only is considered, and from that standpoint I desire to take exception to this article, for it is not founded on fact.

The streets of the city are and have been in just as good condition since Commissioner McCartney took office as the conditions of the weather would permit, and any criticism to the contrary is unjust and by no means in accord with the facts.

The same district superintendents who worked under Colonel Waring are now working under Commissioner McCartney, and such criticisms as appear in your paper are not only unfair to the commissioner himself, but at the same time discredit these district superintendents, who are discharging their duties in the same intelligent and efficient manner as they did formerly.

I have been in the department of street cleaning for over three years, and I know that the work is not only done, but well done, and the same methods are employed and the same system is followed by Commissioner McCartney as were employed and followed by his predecessor, and which have been so universally approved by the public at large.

Therefore I ask you, in the interest of fair play, to retract the article in your issue of February 26, 1898.

F. W. Gibson, *Deputy Commissioner.*

[We are pleased to know that there is a disposition to explain matters on the part of the street-cleaning department; still the facts are so patent to the casual wayfarer that no reply from us is necessary. We are forced to repeat, in spite of the protest of our courteous correspondent, that the streets of New York have never been in a worse condition for years than they are at present.—Ed.]

CYSTOSCOPY IN CONNECTION WITH PROSTATIC HYPERTROPHY—A REPLY TO DR. W. MEYER.

To the Editor of the Medical Record.

Sir: You would oblige me greatly by allowing me space in your valuable journal to reply to a misstatement made regarding me by Dr. Willy Meyer, in his article on Bottini's treatment for hypertrophy of the prostate, which appeared in your issue of March 5, 1898. In that article, after stating "that we can very well diagnose the configuration of the prostate with the help of the cystoscope," and explaining how the instrument should be turned in order to accomplish this, Dr. Meyer says: "I state this particularly to contradict Dr. E. Fuller, who maintained, at one of the late meetings of the section on genito-urinary surgery of the academy, that this was an impossibility and mainly existed in the phantasy of the observer."

I never made the above statement. I did say, however, that "great reliance could not be placed on the cystoscope in definitely determining just what constituted the obstruction to urine drainage in cases of prostatic hypertrophy, and that this was due to the fact that only such obstructions could be seen by the aid of the instrument as encroached on the vesical cavity or were what are called intravesical hypertrophies." In many cases of prostatic hypertrophy the obstruction is caused by growths about the prostatic urethra and about the vesical neck, regarding the presence of which the cystoscope does not give us the least information. I further said, in view of a case which had recently come under my observation and care, that "no one with a vivid imagination should attempt to diagnosticate prostatic obstruction from what he thought he saw through the cystoscope." The circumstances in relation to this case are as follows:

Somewhat over a year ago a practitioner of this city came to me and asked me if I would perform a prostatectomy on a patient of his. I told the gentleman that I should first wish to examine the patient in order to satisfy myself of the diagnosis. The doctor said that that was hardly necessary, since he had already taken the patient to an eminent cystoscopist of this city (at the same time mentioning his name), who had seen the prostatic obstruction and described it minutely as consisting of an hypertrophied median lobe. The doctor further stated that after getting the cystoscopic opinion he had taken the patient to a genito-urinary surgeon, and that that surgeon, being evidently influenced by the cystoscopic opinion previously given, had after some slight investigation, not, however, with the cystoscope, also concurred in the prostatic diagnosis. I examined the man. He was somewhat over forty-five years of age. He had retention, much vesical tenesmus, and some vesical infection. Rectal exploration did not show the prostate to be at all enlarged, but it did show a peculiar tension of the post-prostatic tissues, such as might exist were the fundus of the bladder drawn upward. I introduced a Mercier catheter, which slipped in without any prostatic resistance. Five or six ounces of urine was drawn off. After the bladder had been emptied, however, the catheter could still be pushed in its entire length before its tip touched the vesical fundus. I then made deep abdominal palpation, and detected a tumefaction half way between the symphysis and the umbilicus. After considerable study I diagnosed a neoplasm, probably abdominal, which had involved the bladder. The doctor who brought the case to me was not satisfied, as he was much impressed with the diagnosis of enlarged middle lobe of the prostate given by the first gentleman whom he had consulted. To satisfy the doctor and the man's family, I made a suprapubic incision, which settled the question that there was no hypertrophied middle lobe of the prostate and also that the prostate was normal. The space of Retzius at its upper limits was invaded by a hard sclerosis; so also was the vesical fundus, which was drawn up and secured to a hard abdominal mass, thus effectually preventing vesical contraction and causing the retention. I next made a small abdominal exploratory incision, which exposed to view a malignant mass chiefly involving the omentum, and it was this omental mass which had agglutinated itself to the vesical fundus. I will here state that the malignancy had not in the least at that time invaded the lower portion of the bladder. The wounds healed so that the patient recovered from the operation.

After such an experience as this I think all will justify me in my expression that "no one with a vivid imagination should attempt to diagnosticate prostatic obstruction from what he thought he saw through the cystoscope."

I also think that my case goes to disprove Dr. Meyer's assertion much more strongly than the case he cites goes to prove it. I do not in the least doubt that I or any one used to the cystoscope could see a median lobe of the prostate provided it projected "into the bladder almost as long as the third phalanx of the little finger." In his case Dr. Meyer also states that "there was besides general hypertrophy of the gland." He is, however, careful not to mention that he found that out by the aid of the cystoscope. He concludes with this remark: "This patient was later operated upon by Dr. Edward L. Keyes, by suprapubic radical extirpation of the gland, when the condition of the prostate was found to be exactly as previously seen by me through the cystoscope." As Dr. Keyes did a radical extirpation of the gland, it was in all probability found to be necessary, in order to restore urination, to remove much more than the projecting middle lobe that Dr. Meyer previously saw. Suppose in Dr. Meyer's case Dr. Keyes had simply removed the middle lobe, which was all Dr. Meyer, according to his statement, saw; then it is very likely that the patient might not have been relieved of his retention, in which case it would be fair to infer that a subsequent introduction of the cystoscope would not show the nature of the then prostatic obstruction.

The only way, it seems to me, that Dr. Meyer can definitely prove his statement, and at the same time the value of the cystoscope in the diagnosis of prostatic hypertrophy, is by taking a consecutive number of cases and by making in each after a cystoscopic examination a schematic drawing or, what would be easier and more accurate, a clay model. Then at the time of suprapubic operation an independent surgeon could compare the existing state of affairs with the drawing or the model. Or, what would be better, the whole investigation could be made post mortem, in which event the part could in each instance be dissected out and compared with the evidence derived from the cystoscope.

EUGENE FULLER, M.D.

252 LEXINGTON AVENUE, NEW YORK,

NATIONAL QUARANTINE AND THE MOBILE CONVENTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with much gratification your very just criticism of the late quarantine convention at Mobile. Strange as it may appear in the light of the action of the convention, it is nevertheless true that a decided majority of the members of that convention was in favor of national quarantine. The compromise measure offered as a substitute by Mr. Clark was not discussed and was not properly understood by the convention. And had this very substitute been offered by one of the known advocates of State control of quarantine, it would have been voted down. I shall ever contend that the substitute did not correctly express the sentiment of the majority of that convention.

It was paraded as a compromise measure, and as such held up to the members as an appeal to their generosity—the generosity of victors—when, in fact, it was a virtual surrender of the majority to the minority. Whether or not an attempt had been made to stack the convention and to insure that a majority of its members should favor State boards of health as against national quarantine, I will not attempt to decide; but this I do know, that the able attorneys who were there as invited guests (?) of the convention were accorded special privileges, and each of these used the time so generously allotted to him in trying to stir up a sectional feeling in the minds of the delegates. The national government was pictured as intent upon the destruction of the liberties of the people, and in one instance these appeals were so successful that the solitary delegate from Texas defied the power of the national government, and served notice upon all concerned that Texas would not submit to any quarantine regulations imposed by Congress. That the convention did not fling the same defiance into the face of the national government was owing to the fact that the fiery and impassioned appeals of the attorneys for the State boards of health were not appreciated by the delegates.

I submit that the convention was composed of an intelligent and patriotic body of men, and, though they did not accomplish what they could have done, they deserve some credit for what they prevented the advocates of State control of quarantine affairs from doing.

This city, Vicksburg, is the largest city in the State, and is the home of State Senator Kiger, who is also president of the State board of health. The city council and every one of the commercial bodies and the board of supervisors of Warren County have adopted resolutions calling upon Congress to pass a national quarantine bill.

I firmly believe that nine-tenths of the people of Mississippi are in favor of national quarantine.

Whenever the fever obtains a foothold in our State, a perfect frenzy of lawlessness seizes upon our people, and the authority of the State and the State board of health is set at defiance. Small towns along the line of our great railroads arbitrarily refuse to allow trains to pass through their limits under any circumstances. In consequence of this fact being known, our people are compelled to flee at the first alarm, lest they be shut up in a plague-stricken town as were the people of Edwards, Miss., in the last year. What the people of Mississippi complain of and dread is that our State authorities are powerless to enforce the laws. We call upon the national government to afford to us that protection which our State government cannot give to us.

S. D. ROBBINS, M.D.

VICKSBURG, MISS., February 24, 1898.

SANITARY SKIRTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The "against-spitting" crusade being conducted by the Woman's Health Protective Association, as referred to in the MEDICAL RECORD of February 26th, attracts my attention, and deserves the active support of all who take an interest in the protection of public health and decency, particularly as outlined by our able health board. It is in this connection that it seems pertinent to the above-referred-to article, heroically to suggest to such association that in consideration of its expressed object it would appear to be its express duty to recommend that the ladies adopt the custom of wearing short boot-top skirts in the streets, by which means only can the nasty, besmeared, disease-germ-distributing garments be rendered comparatively sanitary and clean in appearance. What calls for the attention of a health-protective association more than street-sweeping skirts trailing down elevated stairs, etc., collecting street dirt to be distributed in the household? It seems to me that these days are given too much to star climbing for glory and not enough to correcting the commonplace dangers.

M. D. HUBBELL, M.D.

Calculus, with a Snake's Tail as a Nucleus.—Dr. C. G. Kenyon, before the San Francisco Medical Society, September 14, 1897, presented this specimen. The patient from whom it had been removed had been advised to pass a snake's tail into his urethra for the cure of a stiffened right arm. He did so and lost the tail. The tail formed the nucleus of the calculus, as shown.

THE TREATMENT OF CHRONIC EMPYEMA.[1]

BY B. FARQUHAR CURTIS, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; SURGEON TO ST. LUKE'S HOSPITAL AND THE NEW YORK CANCER HOSPITAL.

In the course of a recent discussion on the treatment of chronic empyema, Ewald made the remark that the existence of chronic empyema was due to a failure in medical skill, and von Ziemssen as well as Schede practically agreed with this statement. It would appear, however, that the assertion was rather too sweeping, and that no amount of care on the part of the physician, nor any improvement in the methods of treating acute empyema which may be hoped for, can prevent the occurrence of those cases of empyema which run a latent course, the patient having no symptoms which appear to him to necessitate medical advice. It is certainly not uncommon to find a laboring man still doing his work whose chest is full of pus which must have been present for weeks or months, and even among the more intelligent classes it is not rare to have patients come to the physician for what they suppose to be malaria or a slight attack of grippe and to find pus in the pleural cavity. If all cases of pneumonia were carefully followed for some weeks after convalescence, the number of these latent cases of empyema would be reduced, as a certain proportion of them are secondary to that disease; but it cannot be expected that all would be prevented by this precaution, for they often originate from other causes.

Even when chronic empyema develops from an acute attack, the patient being under proper surgical care, but the lungs refusing to expand and the discharge from the sinus persisting, the failure in recovery cannot always be laid to the charge of the surgeon. Empyema complicated with tuberculosis (and who can be sure in any case that tuberculosis is not present?) will not terminate in recovery in the majority of instances, no matter what pains be taken with treatment. It is also probable that in the purulent pleurisies due to streptococcus infection, or in which such an infection takes place after an operation for drainage has been performed, chronic suppuration of the pleural cavity and of the sinus may occur, just as in suppuration elsewhere due to the same causes. Not all wounds heal primarily, nor do incisions and drainage and antisepsis arrest all suppurating processes in the cellular tissue, no matter how careful the surgeon and how successful he may be in general, for the chances of errors in asepsis on the one side, and failure in the resisting power in the tissues of the individual patient on the other, are factors which we shall probably never be able to eliminate entirely, although we have already so greatly reduced their significance. The second factor—lack of resistance in the patient—is probably of great importance in these cases of pleural surgery, as some of the cases to be related will abundantly illustrate.

[1] Read before the New York Academy of Medicine, December 16, 1897.

If, then, chronic empyema may exist before it comes into the surgeon's hands, or may even develop in spite of his skill and care, it is one of the things we must reckon with, and its proper treatment is all the more important in view of the fact that, left to itself, the lesion is almost inevitably fatal.

Pathological Conditions of Chronic Empyema.—When the pleural sac has been filled with pus for some time, the lung becomes fixed with adhesions and will not expand, and if the pus be drained away the cavity is partially filled by the falling in of its walls on all sides, the rising of the diaphragm, the displacement of the heart and the mediastinum across the median line when the right side is to be filled in, while on the left side the heart is drawn still farther to the left. The chest walls collapse until the ribs are in contact at their edges. This is all that nature can do to obliterate the cavity, for no granulation production of any amount takes place from the pleural surfaces. Schede, indeed, says that no granulations form on the pleura, but this is certainly incorrect, for in my cases I have seen the interior of the pleural sac and the surface of the collapsed lung covered by healthy granulations. No great amount of new tissue, however, is produced in this way, and the granulation layer always remains rather thin. The great thickening of the pleura always found in these cases is due to a simple deposit of fibrin on its surface, which may become more or less organized, and not to new growth of tissue from granulations. Under these conditions we have a cavity containing pus if the case is a latent one which has never been drained. More frequently drainage has been done, but the lung has not expanded and the pleural sac is filled with air. The patient is poisoned by septic absorption, some fluid remaining always in the sac, and feels the loss of the lung. He is anæmic, emaciated, often with hectic fever, and gradually sinks, generally falling a victim to tuberculosis.

Operations.—In the early seventies it is evident that the idea generally suggested itself to surgeons that the natural efforts to obliterate these cavities could be assisted by the removal of some of the bony parts of the chest wall. Simon, of Heidelberg, appears to have been the first to operate with this intent, by removing two or three ribs with a successful result in 1869. He reported the case in 1870. About the same time Küster, Schede, and Létievant independently performed similar operations and Estlander's first operation also dates from that time. The method, however, has been given Estlander's name, and it is certainly due to his writings that the operation has become popular. Estlander's idea was simply to resect a considerable portion of the ribs over the cavity, and at first he seldom attacked more than four or five at a sitting. The operation was rarely attempted for total empyema, and was limited to sacs of considerably smaller size, in which the results obtained were good. It soon became evident, however, that it would be necessary to do something more extensive in the cases of total empyema or even in partial cases in which the cavity was very large.

Estlander's work was first published in 1878–79, and about the same time Schede devised the operation

which bears his name and carried it to a successful issue. In the spring of 1889 it was my privilege to observe some of his cases during a short visit to Hamburg and I was very much struck with the good results obtained. The distinction between his method and Estlander's is that Schede not only resects the ribs but removes the thickened costal pleura, which is almost as much an obstruction to the filling in of the cavity as the bones themselves. In fact that membrane may be calcified and as rigid as bone. After Estlander's operation the ribs are reproduced from the periosteum and this may take place so rapidly as to prevent the healing of the cavity by restoring its rigid wall.

The only improvement made on Schede's method is that suggested by the Frenchman Delorme, who in three or four cases has resected the side of the chest temporarily by dividing the ribs in the line of incision and lifting them in one flap with the soft parts, and then stripped the thickened pleura from the collapsed lung, leaving the pulmonary tissue intact and free. The flap of soft parts and bone was then returned to its place. He has obtained successful results, far better than those of Schede, because the collapsed lung was rendered capable of expansion and could fill the chest again. The last operation is startling in its boldness, because one would suppose that the hemorrhage from the surface of the lung would be so excessive as to cause death, but Delorme states that the hemorrhage is not great, and, as already mentioned, several successful cases are now on record. It is probable that future improvement in the treatment of chronic empyema lies in this direction, for this method restores the expansibility of the lung and produces the ideal result of a normal lung in a normal chest cavity, whereas the Schede and Estlander operations can offer only a pleural cavity obliterated by the destruction of the chest wall and a lung which seldom fully regains its expansibility. Much more experience, however, must be gained before one can venture to make this operation applicable to all cases, and for the present we must be satisfied with the operation of Estlander as modified by Schede, the former for the small cavities, the latter for total empyema.

Development of Chronic Empyema.—With the exception of a few tuberculous cases which may from the first run a chronic course like a cold abscess, a chronic empyema begins as an acute inflammation. Even the latent cases, which present so few symptoms as not to be recognized until weeks or months after their beginning, are probably originally acute. When the pus has been allowed to occupy the chest for some time, the compressed lung contracts strong adhesions and the pleura often becomes an inch or more thick by successive layers of fibrin deposited on its surface. The layers of fibrin become vitalized very slowly. The result of these changes is that when a late evacuation of the pus is made, the lung is too firmly bound down to expand, and simple drainage is not sufficient to cure.

From Improperly Drained Empyema.—The all-important requirement in the treatment of acute empyema is evidently the early evacuation of the pus, and the latter should be removed as soon as its presence can be demonstrated. Whether this is done by aspiration, by continuous suction drainage, or by incision with or without resection of a rib, need not be discussed here. We may, however, note that the majority of surgeons, and even physicians, at present believe that a free incision is the safest and quickest method of obtaining a cure, although we do not deny that recovery may take place after several aspirations, and that continuous suction by the method generally known as Von Bülow's, has had very fair success. Like the majority of my craft, I believe that a free incision is the best treatment for ordinary abscesses, and I am unable to understand why one should take the risk of treating collections of pus in the chest by less certain methods. Subcutaneous abscesses may recover without incision by the formation of small fistulous openings, and inefficient surgical incisions will not prevent recovery in such favorable cases, although it cannot be denied that imitation of the natural slow and uncertain methods by making small punctures in abscesses exposes the patient to risks which are only less in degree than those incurred by the natural process of pointing and fistulous discharge. Argument from analogy is often dangerous, it is true, but many of the cases of chronic empyema give a history of small openings, or badly placed openings, or neglected drainage tubes which have not been kept in good working-order, or which have been removed too soon, showing that the same causes produce in the pleura the same effects that they would in any abscess of the cellular tissues.

But in addition to evacuating the pus promptly the operation should be so performed and the after-treatment so conducted as to bring about a speedy recovery, for if the lung does not expand soon it will be more or less crippled by adhesions, and the costal pleura may also be covered by fibrin so that it will not aid in the process of repair. For these reasons general surgical opinion has come to favor an opening in the chest low down and far back, where drainage will be best secured with resection of a portion of a rib, and great care exercised in dressing the wound and keeping the tubes free. There is no doubt that by this treatment acute empyema can be most quickly and certainly brought to recovery without danger of complications or chronic sequelæ.

One eminent German authority still clings to a high anterior incision, because there is less danger of injury to the diaphragm, and because he thinks that a low opening may become obstructed by the diaphragm when the latter is drawn up into the chest. With proper care the first danger is certainly not great, although I was once present when a well-known surgeon met with the accident of injury to the diaphragm and peritoneum, resulting in the death of his patient from peritonitis, the operation having been carefully conducted according to the usual rules. In this case a rib was resected in the axillary line low down, an aspirating needle was inserted in the chest and pus was obtained, and a tube was placed where the needle puncture was situated, whether through an opening made with a bistoury or with a dressing forceps I am unable to say, as the case occurred several years ago. The tube drew off the pus and the patient was sent to bed. Peritonitis and death followed, and the autopsy showed that the diaphragm had been adherent to the side of the chest, the lowest part of the pleural cavity having been obliterated by some previous inflammation, and then the pus collecting above had forced the central part of the diaphragm down, leaving an interval of free peritoneum between the two folds of the diaphragm where it ascended along the ribs and was adherent to them, and then descended in the centre. The wound for the drainage tube had been made directly through both folds of the diaphragm and had consequently opened the peritoneum and made way for the infection. In the ordinary cases, however, there is no danger of this accident, for this peculiar arrangement of the diaphragm is very rare, and, moreover, the incision should be made slowly, each structure being divided in turn, so that if the peritoneum were opened it would be recognized before the pus was reached.

The second objection also cannot hold, for in ordinary cases of acute empyema the lung promptly expands and the diaphragm descends after its prelim-

inary rise, and even if the muscle should remain fixed at an elevated point it would only imply a longer canal for drainage and an inch or so of additional tubing, the effectiveness of the drainage not suffering materially by this necessity.

Removal of the Drainage Tube.—Having drained an acute empyema promptly and effectively, the second point in its management which is important is the proper method of concluding the case by discontinuing the drainage. It is possible to err in both directions in this matter, maintaining drainage too long or removing the tube too early. Some excellent authorities advise leaving the tube in place until it is actually crowded out by the advancing cicatrization of the sinus. In some respects this advice is sound, for of the two evils an obstinate sinus is less than a reaccumulation of pus in the interior of the chest, and we have in two or three cases seen the latter to be a cause of chronic empyema. After the capacious cavity of the original empyema has contracted to a flat space between the chest and the lung, the tube should always be long enough to reach nearly to the end of the cavity, or perhaps one should say to the apex of the cavity, as the drainage opening is generally at the lowest part of it, and its apex rises toward the clavicle. But it is possible to be too dilatory, and it is well to keep the drainage tube half an inch shorter than the sinus, so as to leave the deepest part of the canal free from its pressure. Among the dangers of too prolonged drainage are the production of a callous sinus lined with granulations so pale and small that they resemble mucous membrane, and with no tendency to healing and the possibility of causing necrosis of those ribs against which the tube lies. In either case a chronic sinus will be formed and the operations to be described below will become necessary.

Drainage Tube Lost in Chest.—One of the rather common causes of chronic empyema is the slipping of the drainage tube into the interior of the chest, and this frequently occurs without the accident being recognized at the time. For instance, a patient may loosen the dressing and the tube may slip out into the bed and be found there on one occasion, and when the tube disappears again its absence may be accounted for on the supposition that it has again slipped out but has been lost, whereas it has really fallen into the cavity of the chest. Drainage tubes used in these cases should be of good fresh rubber, being changed whenever they become brittle. If the rubber is good, the ordinary method of securing the tube by a safety pin run through one side of the external end so as not to reduce its calibre, and fastening it by a thread around the chest or by strips of rubber plaster next the wound, can be safely adopted. But it is of the greatest importance that the tube be changed whenever it becomes brittle, as rubber is apt to do, especially if it is boiled often for sterilization, as is now so common a custom. In one case coming to me with chronic empyema, a retained drainage tube was found in the chest, and it would seem probable that the tube was responsible not only for the chronic empyema but for a long-continued illness which ultimately resulted in death.

Bacterial Origin.—The bacteriological classification of empyema is of little importance in our study of its chronic form, with the single exception of tuberculosis. Whether the disease is metapneumonic or due to the pyogenic bacteria has but little bearing upon the case when it has become chronic. The tuberculous variety, however, is much more difficult to cure and is likely to be associated with similar lesions elsewhere, and some authorities consider it incurable. Schede, however, claims a fair proportion of cures, even in this form of empyema.

Varieties of Chronic Empyema.—For the purpose of our study it is important to distinguish the cases of chronic empyema with a free external opening which has formed spontaneously or been made by the surgeon, from the cases without efficient drainage or entirely without drainage. We shall designate the form as "open empyema," the latter as "closed empyema." The communication between the cavity of the empyema and a bronchus is a complication found in both forms and has little bearing upon the treatment, so that we shall describe it merely as a complication.

We must also distinguish between the cases according to the size of the cavity, separating those which involve the entire pleural sac (total empyema) from those of smaller size (partial or localized or encapsulated empyema), and making a third class of the narrow elongated cavities which may be called pleural fistulæ.

A closed empyema is found in neglected or latent cases in which the pus has been present for a long time, no operation having been performed. If no connection with a bronchus or fistulous external opening exists, the pus generally remains in what may be called a laudable condition, that is, without decomposition, and causes little septic poisoning. When the pus is evacuated the cases sometimes go on to uninterrupted recovery. More frequently, however, their long continuance has crippled the lung by adhesions so that its expansion is impossible, and the usual operation of drainage results merely in the production of an open instead of a closed empyema, and is of little or no benefit to the patient. In view, however, of the fact that certain of these patients recover after the simple treatment by drainage, that method should always be given a trial before severer measures are adopted.

When the cavity communicates with a bronchus without external drainage, the pus often becomes decomposed, for the cavity is rarely emptied thoroughly by this route, sepsis is usual, and the patient's general condition soon becomes miserable. Even a simple incision of the chest for drainage is fraught with danger in such cases, for the mechanism of respiration is disturbed and opening the cavity freely to the outer air alters the conditions of air pressure within the chest. The passage of fluids from the cavity to the bronchi through the false opening may also be increased during the operation by the struggling of the patient to fill the lung with air, and he may drown, as it were, in his own secretions. In one of my cases the operation of drainage resulted in immediate death. This occurred in a man, thirty-four years of age, who had had an abundant foul sputum for years and was supposed to have a phthisical cavity, but on more careful study it was concluded that he had a chronic empyema discharging through a bronchus. The operation was done with the patient in a sitting position and only a light ether anæsthesia was employed. The rib was exposed and a portion resected. The pleural sac was opened immediately with the removal of the bone, the pleura and periosteum having been destroyed by the long suppuration, and air and foul pus escaped from the wound. A violent coughing fit occurred at once, followed by severe dyspnœa which could not be relieved, and the patient speedily lost consciousness and respiration ceased. Artificial respiration was tried in vain; then a tracheotomy was done in hopes that the dyspnœa might be due to pus or membrane in the larynx, but without improvement, and death ensued. It seems probable that when the chest was freely opened the air passed through the pleural cavity and the bronchial opening to the other lung as a shorter route than by the trachea, and that the violent coughing and gasping efforts caused a considerable amount of pus to enter the bronchi and to pass to the sound side, and the patient was thus literally drowned

in his own pus. The case was very interesting pathologically, as it was found that the pleura, both pulmonary and costal, was completely calcified in a sheet one-sixteenth of an inch in thickness, the lung lying collapsed against the vertebræ in the usual situation.

In spite of the bad result in this case, drainage by incision is usually the only possible treatment in such a condition, for the pus cannot be thoroughly removed by aspiration on account of the air also in the chest. Under such circumstances, when the empyema communicates with a bronchus and has not been previously operated upon, the wisest plan is to open and drain it by a simple incision between the ribs if there is space enough, or at most by resecting an inch or so of one rib, and to delay the radical operation until the patient recuperates somewhat.

When an empyema is open and draining well, the radical operation is suitable as soon as it is probable that no further contraction of the cavity or expansion of the lung will take place. This is indicated by the fact that the margins of the ribs are in contact, and by the arrest of the filling in of the cavity, as shown by repeated examinations with a bent probe or by filling the cavity with a measured quantity of liquid. The examination by the probe is made with a long instrument bent at the end like a catheter, which is introduced to the full depth of the cavity, and the beak then rotated while the staff is held in a fixed position. The end of the beak can thus be made to give the diameter of the cavity, by estimating the distance it moves to reach the opposite sides. By advancing and withdrawing the probe the depth of the median side of the cavity from the chest wall can also be determined. I have found this examination more valuable than the method of measuring the amount of fluid which the cavity will contain, as it shows the shape as well as the size of the space. Some authorities advise the radical operation as soon as an empyema which has been operated upon remains stationary for two weeks, but that period seems rather short and I prefer to delay the extensive resection of the ribs for from four to six weeks, if the case had been drained in the acute stage. If the empyema had already existed for some time before it had been drained, however, a stationary period of two weeks is enough, because there is so little hope of spontaneous recovery for the lung. Of course it is understood that the patient must be put in the most favorable conditions as to food and general hygiene during this period, and a change of climate is wise whenever possible.

The narrow elongated cavities which we would designate as pleural fistulæ generally lie close to the ribs, and may have a direction parallel to them or at right angles to their course. Much more rarely the sinus runs directly inward between the lung and the diaphragm. Their walls are usually of great thickness, the lining granulations resemble mucous membrane, and the discharge is usually scanty. They are generally caused by too prolonged retention of the drainage tube after an acute empyema, but are sometimes maintained by necrosis of a rib secondary to the pleural suppuration. Sometimes a cavity of small size lies at the end of a narrow fistula which drains it badly, and simple enlargement of the sinus with careful drainage will effect a cure, but generally the removal of some bone is necessary. The cure is most easily obtained when the fistula runs parallel to the ribs, as the resection of one or two ribs will suffice, but when the sinus extends upward or downward across the ribs it is generally necessary to resect a number of them. The amount of bone to be removed from each rib is small in the latter case, however, one inch more than the diameter of the sinus being enough. In some cases, as in one to be reported, the sinus runs backward so near the vertebral column that its exposure would require an operation much more severe than the danger and discomfort caused by the sinus would warrant, and under such circumstances the latter is best left untouched, treatment being limited to the maintenance of proper drainage, with occasional applications of tincture of iodine or pure carbolic acid to the walls of the sinus, made similarly to those used in the uterus for endometritis.

The technique of the radical operations is as follows: Estlander first performed his operation by a separate incision for each rib to be removed, but this has dropped out of use for obvious reasons. Some surgeons raise a horseshoe-shaped flap from the side of the chest over the ribs to be removed, with its base above or posteriorly. Others expose the ribs by an L or ⊥ incision with triangular flaps, and the latter incisions appear to be the most convenient. The vertical incision should correspond with the centre of the cavity to be exposed, and the transverse incision should be parallel with the lowest rib to be removed. Two triangular flaps are dissected back far enough to uncover the ribs to be resected, and then that portion of every rib lying over the cavity is removed, the amount of bone to be taken away depending upon the size of the cavity across that particular rib. If possible, at least an inch more rib should be taken than the width of the cavity at that point. As it will usually be found that the cavity narrows as it extends upward, it will not be necessary to remove as much from the upper ribs as from the lower. The pleura is often thickened, and, the ribs being removed subperiosteally, the pleural sac is not opened during this part of the operation, and the periosteum, intercostals, and pleura covering the cavity were left by Estlander. But modern surgeons generally prefer to cut away the soft parts, as recommended by Schede.

When the bones have been removed, the drainage opening is enlarged to admit the finger into the cavity, and a thorough exploration is made of its interior. The opening should then be enlarged by an incision parallel with the intercostal vessels to the full width of the cavity, and the thickened pleura is then cut away together with the periosteum of the ribs, at the points where the latter have been removed, with a strong pair of scissors, one intercostal artery being divided at a time and easily seized. Sometimes it is possible to seize the arteries with a pair of forceps and divide between the latter. If the tissues are so hard and friable that ligature of the vessels is difficult, they can usually be secured by a ligature passed around them. This removal of the pleura and other soft parts which cover the cavity after resection of the ribs, applying the principle of the Schede operation to the small cavities, gives far better results than the original Estlander operation, which limited itself to the removal of the bones. The cavity having thus been exposed it walls are thoroughly curetted and wiped out with gauze pads, the false membrane being removed as much as possible from the surface of the lung and other parts down to healthy tissue.

The cavity is packed with dry sterilized gauze after a large piece of iodoform gauze in two layers has been laid inside of the cavity as a lining, which forms a sort of bag in which the packing is placed. This piece of iodoform gauze must be large enough to fill easily all the recesses of the cavity, which is often very irregular in shape, so that the pressure of the packing shall be evenly distributed in all directions and no dead spaces shall exist in which fluid can collect. The two flaps of skin are laid together over the gauze packing and may be retained if desired by a couple of sutures tied in a bow knot, which can be released when it is desired to dress the wound. The external dressing does not need to be heavy. This dressing remains unchanged until a rise of temperature or a profuse se-

rous discharge from the wound indicates that it is necessary to renew it. In some cases the course is absolutely aseptic; in the majority, however, there is more or less sloughing and slight suppuration takes place, and then the discharge of the first few days will be profuse until the sides of the cavity have thoroughly cleared off.

The Schede operation I have generally performed on about the same lines as already described, using a vertical incision in the midaxillary line with a transverse one along the lowest rib removed. Schede cuts a flap by a curved incision beginning at the anterior border of the axilla on the edge of the pectoralis major and sweeping downward and backward until it strikes the eighth or ninth rib at the posterior axillary line, then curving backward and upward to the posterior border of the scapula. The incision is deepened to the ribs, and the skin, subcutaneous tissue, and muscle are rapidly dissected from the bones. This can be done by blunt dissection and the loss of blood is slight except in the division of a few muscular fibres of the serratus. The arm is held fully extended upward, and the scapula is partially detached from the chest. The flap can then be thrown upward and strongly retracted. The ribs are removed separately, beginning with the lowest and extending if necessary up to the second rib. In dividing the ribs Schede cuts them with the forceps in the middle after separating them from the periosteum, and then seizes each half in turn with the hand and breaks off the anterior half at the costal junction and the posterior half at the angle of the rib. I have generally cut the ribs at these situations with strong forceps, without preliminary division in the middle. The pleural sac is opened as already described, and the thickened pleura and other soft parts covering it are divided and removed in the same manner. The resection in total empyema must be very extensive, beginning with the eighth or ninth rib and extending up to and including the second. In some cases, particularly when the lung has become adherent posteriorly rather than toward the mediastinum, it may not be necessary to remove so much of the bones in that direction. After a thorough cleansing of the cavity as already described, the skin flaps are turned into the chest and secured with one or two sutures, so that they cover in the broken ends of the ribs and furnish a partial lining for the cavity. The most difficult part to cover in is the apex in the neighborhood of the second rib. Schede states that the cavity never fills up and that transplantation of skin by subsequent plastic operations is absolutely necessary. In my own experience this has not been the case, the cavity becoming smaller quite rapidly, as will be described below.

It will be noted that there is practically little difference between the operations of Estlander and Schede when performed in this manner except in the extent of the resections, the only essential variation being that the skin flaps are left outside of the packing in the former case while in the Schede operation they are turned into the cavity. The reason for the difference in the treatment of the skin is that the former operation is intended for small cavities, when there is hope that the lung will expand and fill the cavity promptly, and this has been my usual experience. In total empyema, however, the changes which fill in the cavity take place so slowly, if they occur at all, that it is necessary to cover the raw surfaces of the large cavity by every means in our power. It has seemed to me a practical convenience to preserve the name of Estlander for the minor operation, even after having applied to it Schede's principle of removing the soft parts as well as the bone. The term thoracoplasty, often employed, is rather cumbrous for general use.

The manner in which these operations act in producing a cure can be best understood by following the changes observed after their performance. In some cases the discharge is so abundant during the first two or three days as to compel the early renewal of the dressing, while in others the secretion of the cavity is very slight and the packing may be left in place for a week. The latter result proves that the efforts at sterilization of the cavity by the use of the curette and irrigation have been more successful than common, and that the septic material has been thoroughly removed. When the gauze packing is inserted at the time of operation the cavity is wide open and the patient under an anæsthetic, so that it can be packed very tightly and at the first dressing immediately after the removal of the packing there will be a perceptible decrease in the size of the cavity, owing to the falling in of its walls on all sides. The diaphragm rises, the stumps of the resected ribs anteriorly and posteriorly curve in, and the mediastinal tissues may also become displaced on the inner side of the cavity. When many of the ribs have been removed the whole thorax becomes so movable that this contraction is most marked. The opposite side of the chest even swings over a little, flattening in front and displacing the sternum toward the gap made by removing the ribs. By the end of the first week, in cases in which the pleural destruction has not been very great, the cavity will be found covered by budding granulations springing from the parietal and pulmonary pleura on all sides. Here and there will be sloughs which must detach themselves, and this process may require another week or two. The discharge from the granulations will be the usual serous pus, while abundant serum will be poured out from all the parts where sloughs are breaking down and separating. After the granulations have started, iodoform may be used more freely in the dressing, as the risk of absorption will be less: and as the cavity will also be smaller, the total amount of iodoform required will not be so great and there will be less danger of poisoning. Still later balsam of Peru is useful to hasten the healing.

Schede states most positively that the lung often expands afterward, no matter how much contracted it may seem to be at the time of operation, and my own experience leads me to believe that this is the rule, for it occurred in two out of my three cases of total empyema. In one case which terminated in death at the end of three months the lung never expanded, and there was never any noticeable diminution of the size of the cavity except that produced by the rising of the diaphragm and the falling in of the two bony sides of the chest. In small cavities, when only short pieces of the bones are removed, not over two inches, for example, the ends of the ribs may even be in contact by the end of the third or fourth week. In the slighter cases of partial empyema, also, the lung expands quite rapidly to the level of the chest wall. When this occurs the cavity is soon obliterated, becoming reduced to a slightly depressed granulating wound. It is curious to observe how the skin which has been turned into the cavity over the edges of the resected ribs, as described above, is lifted up by these changes and detached from its folding in, so that it finally becomes applied smoothly to the sides of the shallow depression in the chest. Some authorities have reported successful cases of skin grafting on these areas or even inside of the original cavity. Schede, however, says that Thiersch skin grafting does not succeed and he has employed plastic operations, turning flaps of skin from various directions into the cavity to overcome this difficulty. In my own experience in the lesser cases and in one total empyema (the case of Metha B——) recovery took place spontaneously without grafting or plastic flaps. The other two cases of

total empyema never improved sufficiently to justify an attempt to cover the granulating surfaces.

The first deformity produced by these extensive resections is startling. On the right side of the chest seen in profile there is a slightly concave instead of convex line of the thorax extending downward from the clavicle to the diaphragm, which swells out over the surface of the liver, the latter standing out like another shoulder or a shelf on the side of the body. On the left the heart in its pericardium makes a distinct protuberance, and the organ can be felt beating directly under the skin, where it rests on the shelf formed by the dome-like swelling of the diaphragm. These cavities, however, fill out in time, even the contracted lung expanding, and in the course of a year or two it is impossible to realize that such extensive operations have been performed. A slight lateral curvature may be the only trace of deformity remaining after severe operations, and even in children this may also entirely disappear. Some condemn the operation in children because of the deformity, but in my experience the lateral curvature remaining is no greater than that observed in every total empyema with the ribs in contact. In view of the fact that the lung has been shown capable of expansion even in these very severe cases, it is necessary in the after-treatment to aid expansion by the use of some means of forcible expiration, such as the simple spirometer invented by Dr. Walter B. James, of New York. In this apparatus the patient blows through a tube connected with a bottle filled with red fluid, the latter passing to an empty bottle connected with the first by a siphon tube, so that the patient may have ocular demonstration of what he is doing, and the amount of pressure can be regulated by placing the empty bottle on a higher level. This simple spirometer answers all purposes, and with children especially may be made a source of amusement which will induce them to exercise their lungs.

Statistics.—Schede reports 15 cases of his operation done by himself, the result in 2 being unknown while 8 ended in recovery and 5 were fatal. To these he adds 18 operations performed by others, with 5 cases under treatment, with 5 recoveries and 5 deaths. Combining the two series, we have 33 cases with 13 recoveries and 13 deaths, the remainder being unknown as to outcome or under treatment. The causes of death were in 2 cases iodoform poisoning, in 4 cases collapse after the operation, and in the remainder tuberculosis and Bright's disease. In regard to tuberculosis, Schede claims that such cases can be cured, so that the mere fact of the empyema originating in a tuberculous person, or having become tuberculous subsequently, would not be enough to contraindicate operation. The decision of the question in such cases depends upon the general condition of the patient and particularly upon the condition of the other lung. Some of Schede's cases of tuberculosis remained well for long afterward.

The time necessary for recovery depends mainly upon the size of the cavity—a pleural fistula may be cured in eight or ten weeks, while a total empyema will often require as many months. Schede states that at least a year generally elapses before complete recovery in total empyema. In my cases of total empyema one patient (Metha B——) was discharged cured, except for a narrow sinus in three and one-half months, an exceptionally rapid cure. In another case (James A——) the cavity filled up to a level with the chest in about the same time, but the granulating wound never cicatrized, owing to his poor general condition.

Of the Estlander operation the following cases have been selected as illustrative and worthy of report:

Case I.—Minnie C——, aged eight years, had pneumonia and following it an empyema lasting for three months. Two weeks before she entered St. Luke's Hospital, an incision had been made in the fourth space near the sternum, evidently where the pus had pointed and had been supposed to form an abscess. On October 19, 1893, a portion of the sixth rib was resected and the cavity properly drained. The child improved, the lung expanded, and the cavity contracted, but finally it remained stationary, and about three months after the first operation there was a space just inside of the ribs, measuring two inches in width by three inches in height, but rather shallow. On January 9, 1894, three inches of each rib from the fourth to the seventh inclusive were resected and the corresponding costal pleura was removed. The wound was packed and she made a good recovery, being discharged on February 17, 1894, cured. Some six or seven months later she was still very well, with no trace of a sinus, and the deformity produced by the resection of the ribs was almost unnoticeable, the spine in particular being straight. She was seen at a later date and had a tuberculous eruption on the side of the chest near the cicatrix, and the latter broke down superficially, but there was no recurrence of the trouble within the chest. After some months the tuberculosis of the skin was apparently cured. This case illustrates the manner in which arrest of healing takes place in an acute empyema even when carefully treated, probably due to the poor condition of the patient, a very anæmic girl. It also shows a good result obtained by operation. In another case we were less successful.

Case II.—Lottie K——, aged seven years, was admitted to St. Luke's Hospital, having had an empyema four years before, the sinus persisting but not affecting her general health. She was operated upon December 16, 1889, and a cavity found which extended from the seventh rib, in a direction backward and upward toward the spine, to two and one-half inches above the fourth rib. The cavity was narrow and lined by a cartilaginous membrane half an inch thick. Two inches of each rib from the fourth to the seventh inclusive were removed over the track of the sinus, the thickened pleura being resected with the ribs. On account of the depth and direction of the sinus toward the vertebræ it was felt to be unwise to pursue it farther, and it was hoped that the upper portion would contract after the curetting and drainage. The wound was kept widely open by packing and she made a good recovery from the operation, but when discharged from the hospital still had a small sinus leading to the upper part of the old cavity. Three years later she was examined and the sinus was still present. It was very narrow, just admitting a probe where previously it had admitted the finger, and it was shorter and had much less discharge. Her general health remained perfectly good, but there was a slight lateral curvature owing to the loss of bone from the ribs and to the general falling in of the chest toward the side where the empyema had been. This case shows a complication which prevented a perfect success but did not prevent a marked improvement being obtained by operation.

Case III.—Willis B——, aged ten years, was admitted to St. Luke's Hospital, November 12, 1892. There was no family or personal history of tuberculosis and the child had been perfectly well until three years previously, when he had been struck in the chest by a baseball and a rib had been fractured. Three months later he had developed symptoms of suppuration with high fever, and an incision had been made in an intercostal space by which pus had been discharged and drainage maintained for a while by a tube. The wound had closed spontaneously. The pus had reaccumulated, however, and had been discharged by incision twice afterward, in each case the discharge ceasing and the opening closing, and then a relapse taking place. Finally a piece of the broken

rib had been resected and an opening made which was still patent. On admission he had no cough and no pain and his general health was fair, although he was thin and anæmic. Physical examination showed the heart displaced to the right of the sternum, the left side of the chest contracted so that the ribs lay in close contact, with no expansion of that side of the chest. A sinus existed between the ninth and tenth ribs on the left side of the mid-axillary line which discharged very offensive pus. There was lateral curvature of the spine, the concavity being on the diseased side. On November 15th, Estlander's operation was done by the usual method. The incision reached from the axilla to the nipple, curving backward to the eleventh rib at the posterior axillary line. The flaps were raised uncovering the ribs, and portions of the fourth to the eleventh ribs were resected over the cavity, over two inches being removed from each; in all sixteen inches of bone. A cavity, the size of an orange, was discovered, and in it were found small pieces of dead bone and a piece of the eye end of a catheter, two inches long, which had evidently been there for a long period of time. The ninth and tenth ribs had coalesced by new deposits of bone around the mouth of the sinus, forming a complete ring of bone about it, and were very much thickened. All the ribs showed the peculiar triangular deformity due to the deposit of bone on the inner surface, which is generally found in these chronic-empyema cases. The cavity was lined by a very thick membrane, which was removed as far as possible with the curette, after cutting away the parietal pleura with the soft parts in the intercostal spaces and the periosteum of the resected ribs.

The packing was changed for the first time on the 23d, eight days after the operation, and two days later he was allowed up in a chair, the wound being dressed every two days thereafter. In January, 1893, he was discharged cured, with good pulmonary resonance over the whole chest. In June of that year he returned to the hospital, having a sinus which had formed in the scar eight weeks after his discharge, and admitted a probe for about two inches, reaching bone. The sinus was situated in the centre of the old scar. It was curetted by one of my colleagues, and on June 21st the patient was discharged improved.

He remained well and developed about as boys of his age, the spine becoming straighter, but a small sinus persisted in the scar, and on January 5, 1897, five years after the previous operation, he was readmitted. The sinus led to a cavity beneath the lowest ribs, which I laid open by a vertical incision extending downward across the abdominal muscles, nearly to the crest of the ilium. Portions of the two last ribs were excised, the granulations were curetted, and the cavity was packed. He was dressed every alternate day, the cavity filling up with healthy granulations, and on the 12th of February he was allowed up. He began to complain of headache accompanied by drowsiness on the following day, the temperature remaining normal. Irritability subsequently developed; he refused food, and began to vomit. The urine was found to contain two per cent. of albumin with granular casts. The temperature was normal and the pulse was slow with some tension. On the 18th, the temperature was 100° F., this being the first rise of temperature, but the pulse remained only 60 a minute. The next day he was comatose and died at noon. The post-mortem temperature reached 100.2° F. No autopsy was made, and the cause of death remains obscure. It was supposed at the time to be tuberculous meningitis or nephritis, but it is also possible that he had an abscess of the brain, for it is well known that such abscesses are very frequent after interthoracic suppuration. The case is exceedingly interesting in view of the fact that a foreign body was found in the cavity of the empyema, which had begun early three years before my first operation, having repeatedly been drained and having repeatedly recurred. Probably the tube was lost early in the course of the case and was the cause of all the subsequent trouble. The Estlander operation resulted in a practical cure, the small sinus which persisted being undoubtedly maintained by necrosis of the ribs. The boy developed just as other boys do, during the four years subsequently, and died probably from a complication of the long-continued suppuration.

These are typical cases and it is not necessary to cite any more of them. They show fairly well the capabilities and limitations of the operation.

I have performed three Schede operations for total empyema as follows:

Case IV.—Metha B——, aged twenty-four years, was admitted to St. Luke's Hospital, November 2, 1892. In April of that year she had a pleurisy and later had been operated on for empyema. The sinus had healed in nine weeks, but in October, as she had suffered from a return of pain and cough, the chest had been incised again. When she was admitted, the heart apex lay in the fifth space internal to the nipple. The right lung showed impaired resonance at the apex, with flatness below the second rib and many large crepitant râles from pulmonic adhesions. Posteriorly there was flatness below the angle of the scapula, and the breath sounds were impaired above, with many large râles, especially on coughing. Vocal resonance was increased and the breath sounds were feeble and broncho-vesicular. On the left side there were exaggerated breathing and râles. There was œdema of the legs. No tubercle bacilli could be found in the discharge or in the sputa. The cough was easy, there was no fever, and the urine was normal. There was a sinus situated between the eighth and ninth ribs into which a probe passed for four inches, giving issue to a slight discharge. Examination of the lung on the 13th of November revealed absence of respiration on the right side, the left side being practically normal.

November 15th, two days later, the operation was performed in the manner already described. A total empyema was found, the lung being completely collapsed, adherent, and bound down to its root at the spine. Portions of the ribs were removed from the third to the ninth inclusive, in all about eighteen and one-fourth inches. The operation was followed by some shock and severe pain in the chest. Five per cent. of albumin and granular casts appeared in the urine. The external dressings were changed two days after the operation and on the sixth day after operation the packing was also changed. On December 7th, she was allowed up. On the 20th of that month the cavity was very shallow and measured three and one-half by two and one-half inches across. She was discharged on February 16, 1893, with a minute sinus, which healed spontaneously. I had an opportunity of examining her two years later. She had been perfectly well and had born a healthy infant about a year after the operation. She was stout and rosy, and a slight lateral curvature was the only deformity remaining, except the scar and a slight flattening of the right side of the chest.

The amount of bone removed in this case was not so great as in the typical Schede operation, but every rib resected was divided far back near the angle, and the resection was sufficient to produce a rapid cure of a total empyema.

Case V.—Jennie L——, single, thirty-two years of age; born in the United States. Admitted to St. Luke's Hospital, May 14, 1894. In January of that year she had an acute pleurisy lasting for three weeks. The next month cough, expectoration, and pain in the right chest were present. These symptoms continued,

and on admission a large empyema of the right side was found, which was treated on the 15th of May by resection of the ninth rib, and the cavity was drained. The lung did not expand well and the patient was discharged on July 2d, with the tube in place, to go into the country. She was readmitted July 28, 1894, and came to my service. The patient was greatly emaciated, very anæmic, and running a hectic temperature. She had been a circus performer of splendid physique and originally fine constitution, with unusual pluck. On August 11th Schede's operation was performed. The ribs on the right side were resected, from the second to the seventh inclusive, about three inches being removed from the second rib and larger portions from the others down to the seventh, which was removed almost entire. When the chest was opened a most extraordinary condition of affairs was found. The lung was contracted and bound down so completely that it seemed to be entirely absent, being flattened against the vertebræ. The heart could be seen beating behind the sternum, and the pericardium was dissected up from the mediastinum and the surrounding tissues by the burrowing of the pus, so that the fingers could be passed almost entirely around the heart in front and behind. The heart was not displaced toward the right, and the right side of the chest was completely empty. The wound was treated in the usual manner, but the packing as well as the outer dressing had to be removed three days after the operation on account of the discharge. On August 22d she was allowed up in a chair, and by the 29th had gained six pounds in weight. The temperature, however, remained hectic, and on August 30th she was seized with œdema of the left lung. The attack nearly cost her her life, but after thorough treatment by medication and cupping the chest she recovered.

Similar attacks followed on the 4th, 10th, 16th, and 26th of September, all of them being very serious. The patient maintained her calmness with remarkable courage. The discharge from the chest continued to be abundant and there was absolutely no attempt at filling in in any direction. The large sinuses in front and behind the pericardium remained pervious, and water injected into the anterior passages flowed around the pericardium on the left side and out again into the cavity of the right chest posteriorly. The pleural cavity became covered with healthy granulations and was not septic, but showed no tendency whatever to recovery. The lung did not expand in the slightest degree. At the apex of the chest there were some bands crossing the cavity, some of which were evidently blood-vessels (veins) of considerable size, and quite a little oozing occurred on several occasions from this region. On October 6th the flow of blood was quite abundant and had to be controlled by tight packing; this bleeding recurred two or three times, and the following day the patient died at 1:45 A.M., about three months after the operation, the recurring hemorrhages being sufficient to loosen her slight hold on life. Before the operation, from July 25th to August 10th, her morning temperature was usually 97.5° to 98° F.; her evening temperature was 100.6° to 101° F., once touching 102.4° F. For two days after the operation (August 11th and 12th) her temperature remained low, between 97° and 99° F., but on the 13th it again became hectic, 97° F. in the morning, 100.4° F. in the afternoon, and so continued until her death.

In this case the patient had probably had an empyema for three months before it was drained, and was suffering from complete exhaustion and unable to repair the tremendous ravages caused by the disease. The operation improved her, as shown by the lower temperature and the gain in weight, and it would probably have saved her life if it could have been performed a few weeks earlier.

Case VI.—James A——, aged seven years, born in Italy, was admitted to the New York Infirmary for Women and Children, December 31, 1895. Six days before admission he had begun to complain of pain in the abdomen and to be short of breath. The right pleural cavity was drained by a simple incision, no rib being resected. He remained in the hospital three months after the first operation and was afterward treated as an out-patient. He came back to the infirmary in April, under my care, and was then greatly emaciated and exceedingly anæmic. The right side of the chest had retracted until the ribs were in contact and the lung had not expanded. The discharge from the sinus was quite abundant and the child was evidently failing. The liver was very much enlarged and had undergone amyloid degeneration, and the child seemed tuberculous and perhaps syphilitic, having a chronic conjunctivitis and some skin lesions. In the left lung there were no distinct lesions.

Schede's operation was performed on April 24th, from two to five inches being removed from each rib on the right side, from the second to the ninth inclusive. The cavity was treated as usual and the child made a good recovery from the immediate effects of the operation. The cavity remained clean with a discharge of a moderate amount, but it contracted very slowly. The child gained weight and strength somewhat during the summer and the cavity slowly filled in, the contracted lung expanding until finally the deep depression in the chest had disappeared. He was discharged from the hospital to be treated as an out-patient on October 19th, having then lost ground somewhat and it being evident that he could not make headway against the complication of disorders. The wound was by that time reduced to a flat granulating surface, as large as the palm of the hand, with a few sinuses running in various directions to the ends of the ribs, which were somewhat necrosed, but with very little discharge. The boy lived until the following April, the local condition remaining about the same.

In this case the child was almost exhausted by the disease, with a very evident constitutional taint, probably a combination of tuberculosis and syphilis. The operation improved his condition and undoubtedly prolonged his life, as he lived for a year after it. Schede states that he has not infrequently seen an amyloid liver reduced to normal size during the course of treatment after the resection, and considers that lesion no contraindication to an operation. Amyloid degeneration of the kidneys, however, would probably forbid operation because of the danger of administering the anæsthetic under such conditions. Of these three cases of total empyemas, then, one patient was cured, in one case the empyema was practically cured and life was prolonged, and in one case no benefit resulted. In no case did the operation do harm.

In conclusion I would like to emphasize the following points:

We must not allow ourselves to be alarmed at the apparent severity of the operations advised, for the records show that even these weak patients bear very well the complete resection of the ribs, if it is rapidly and skilfully done. The secret of success lies in the slight anæsthesia required and in the proper control of hemorrhage.

Nor should the fear of deformity prevent these operations, for the deformity greatly diminishes with time in both adults and children.

Finally, when we consider the incurable and dangerous condition for which the operations are required, we are willing to assert that the immediate risk to life arising from the operation is justified, and that even a permanent deformity is not too great a price to pay for a cure in these desperate cases.

THE FEMININE ELEMENT IN GENERAL MEDICINE; OR, THE RELATION OF THE GENERAL PRACTITIONER TO DISEASES OF WOMEN.

By EUGENE COLEMAN SAVIDGE, M.D.,

NEW YORK,

ATTENDING GYNÆCOLOGIST, ST. MARK'S HOSPITAL; ASSISTANT GYNÆCOLOGIST, ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT.

Women are more numerous than men. Women are afflicted with an entire catalogue of diseases that do not fall upon men. Diseases of women, therefore, are apt to form the bulk of the work of the medical profession.

Men in our profession are unequally divided between physicians and surgeons. There are more physicians than surgeons, for less capital is required by the physician. A diploma, a sign, a table, and a prescription blank will launch the physician. A far larger capital is required to equip the surgeon. Consequently we can almost count on our fingers those who have been called the "professional" surgeons in each of the great cities of the world. Behind the prestige of every one stands a large capital of influence and money necessary to attain the hospital appointment, without which—as sharply as the statement has been resented—few of the outside ninety-nine per cent. can hope to be more than "amateur surgeons," as they have been called, forced to refer their heavy cases to the professionals. These, equipped for the graver work, number hardly more than one per cent. in the healing-army and enjoy a rich monopoly.

Now, diseases of women were abruptly transferred from medical men to surgeons almost within the memory of the present generation. Most of the work is of the graver class of surgery that is rarely properly done outside of this compact hierarchy of the elect. These favored of fortune suddenly came into possession of the richest harvest in the medical field. The one per cent. had more than half the world!

The vast amount of work falling thus into comparatively few surgical hands gave an enormous impetus to surgical gynæcology. Men of influence and opportunity bent their energies in the advance from one brilliant surgical success to another, and built up a specialty of such prestige that medical men have almost entirely abandoned diseases peculiar to women to these specialists. As a consequence, the medical side of the specialty has been left undeveloped.

Does the statement need proof? Call the roll of gynæcological celebrities and see if the fame of every single one does not rest upon his surgery, and most of it of the grave kind possible only to this compact elect. Analyze the ideal of every new gynæcologist and see if in his mind gynæcologist and laparotomist are not synonymous. Picture the attitude of the gynæcologist toward statistics of cases of uterine retrodeviations, or of uterine fibroids, for example, palliated or cured without operation. Run over the list of papers presented at the last international gynæcological congress at Geneva, and see how exclusively surgery has occupied the minds of the exponents of this new science during the most recent period of which we have record.

One more point: call to mind the usual attitude of the general practitioner bringing the gynæcologist a case in consultation. As a rule he will have no idea of the local condition; he will not even soil his hands by examination; and he surrenders his patient to the specialist, whose habit, trend, desire, necessity, and—one might almost say—reflexes are all surgical!

That there is a striking difference in point of view between two such men will be apparent to any psychologist. The man with the meagre capital of sign and prescription blank would naturally prefer that everything could be cured by diagnosis and prescription, for he is equipped for that. On the other hand, the man whose line requires the greater capital of organized staff, operating-room, and hospital must continue operating or disband. Consequently, the psychological pressure of environment impels one man to shut his eyes to the question of operating, and the other man to seek reasons for operating rather than for not operating.

Many are greater than this pressure of environment, but study them and see if they are not either general practitioners who have become specialists, or specialists who have evolved into physicians and retain considerable general practice.

To discuss this subject is to broaden our limitations. No one but a lopsided man can see in such a discussion any detraction from the brilliancy of the work done by men in the surgical department of the comprehensive specialty of diseases of women; and no true scientist will ever extract personal umbrage from an academic discussion.

The Feminine Element.—A man may come to a medical adviser for cough, for headache, for indigestion, for flatulence and constipation, for hemorrhoids, for disturbances of vision, for neuralgia, for cardiac palpitation, for nerve exhaustion—and so may a woman. In the case of the man the physician can apply with success knowledge acquired from his professor or from text-books on the practice of medicine. But what cured the man will often fail absolutely with the woman, although the symptoms seem precisely alike. The reason of failure is the feminine element, which is my subject in hand.

The Resident Germ.—In no part of the male anatomy does a serous cavity communicate directly with the exterior. The female, on the contrary, has an unguarded opening into the peritoneal cavity through the Fallopian tubes. Woman is therefore at the mercy of the atmosphere to some extent. She is notoriously, in her peritoneal integrity, dependent upon the good health of her partner in copulation. And, more than that, she always carries in her vagina, even as a virgin, germs that need only the soil turned over to spring into virulence.

One of the most important recent advances in gynæcology is that involved in the work of Winter, Haustman, Küstner, Lomer, Bumm, and Döderlein, upon the subject of micro-organisms in the normal vagina. It has been proven as conclusively as any other fact in bacteriology that a host of germs rest in the normal vagina, and they have been found in the cervix uteri even of virgins. Among these germs are the staphylococcus pyogenes albus, aureus, and citreus, and the streptococcus. The body of the uterus normally lacks these germs, because its cavity does not contain the liquid necessary for their support. Note well this point. These organisms are undoubtedly greatly attenuated, but can become rapidly virulent under favoring circumstances.

Circumstances Favoring Virulence.—What are these favoring circumstances? Any sufficient subtraction from general vitality. Take the interesting subject of fatigue: the heart beats less sturdily and burnt-out muscular products depress vitality. Take so slight a factor as the barometrical condition of the atmosphere: when the mercury drops in the tube because of diminished sustaining power in the atmosphere, is not corresponding support withdrawn from around the veins? The human barometers are the bane of every consulting-room. Is it not a condition analogous with fatigue?

Do not "piles come down" in bad weather and fatigue; and an enlarged prostate ache, a "milk leg" or bad joint or old scar or syphilitic node become insistent; varicosities take on erection; the mammæ, as at menstrual periods, become sore, and dark circles

appear under the eyes? We all know scores of female patients with "piles"—so to speak—in their broad ligaments; with an aching bunch of dilated veins, not distinct after death, yet swelling up at times to drag these women, and bring them under the doctor's diagnosis of chronic salpingo-oöphoritis. It seems sometimes as though these women had livers and spleens in a state of chronic priapism.

Increased Blood Pressure an Important Factor.—We have an important point here, since an increase in blood pressure will diminish the resistant power of cellular life. A well-known example will illustrate: varicocele most frequently attacks the left testicle. Woman has pain most frequently upon her left side, and varix and œdema occur most often in the left leg. These are not exclusively left-side troubles, for sometimes both sides are involved. But what determines the choice of the left side and the frequent immunity of the right? Is it not that the difference in static pressure leaves the right side more vigorous? We all know that this difference in blood pressure between the two sides arises from the slight obstruction to the return blood current on the left side, because the left ovarian (or spermatic) vein empties into the renal vein instead of the vena cava, and the left common iliac is longer and more oblique in its course than the right. Representing this static pressure on the left side as ten degrees and as nine on the right, we can thus symbolize the difference between them. This one degree of excess blood pressure on the left side is what depresses the vital resistance of cellular life on that side, so that it falls under the influence of what does not affect the other side. Is not this a sound proposition?

If this slight natural difference in static pressure, thus crudely symbolized, determines the resistance of one side to an abnormal condition, and allows an ache or an inflammation on the other side, is there not a prime significance in pelvic congestion to the medical man?

Auto-Manufacture of Pseudo-Gonorrhœa.—Now, all conditions which overengorge the uterine system of women furnish just those favoring circumstances which are needed to enable the resident germ to spring into virulence. A good example is the so-called virginal metritis induced by the intense congestion of the first menstrual epoch, or by cold or congestion during subsequent menstrual periods. An analogous condition is the congestion of the menopause in married or unmarried women. These conditions furnish the missing uterine fluid to nourish bacteria, break down the resistant power of cellular life, and allow an invasion and multiplication of the germs sentinelled in this dangerous zone.

A Partial Dissent from Noeggerath.—This gives us ample justification to dissent from the views of Noeggerath, now so uniformly accepted by the profession: namely, that the uterine, tubal, and ovarian infections found in woman are almost entirely due to latent gonorrhœa in the male. While this unfortunately is too frequently the fact, and while the statement of such fact fits exactly the medical man's pessimistic conception of humanity as formed by too keen a knowledge of it, at the same time a purulent female genital trouble capable of infecting the male is often a home product of an exclusive home industry. This can be affirmed with the authority of knowledge as positive as any repeated clinical observation can give. A uterine retroversion, for example, will congest the parts like a string drawn around the finger. At once is furnished the uterine fluid, the culture medium for the resident germ. Add excessive intercourse to this condition, and a purulent reaction is not far away.

Operative versus Expectant Treatment of Abortion, etc.—This adds new reason to distrust the counsel of those who follow the expectant plan of treatment in the face of foreign matter in the vaginal or uterine canals; who therefore guess and hope—instead of seeing and knowing—that the lurking seed will not take root in favoring soil.

General and Local Reciprocal Relations.—One other point: there is a relation of reciprocal cause and effect between local uterine troubles and the general system. I have elsewhere elaborated this and dwelt upon the manner in which a local trouble will affect the general system, and through this impress upon the general system react in aggravating its own condition. In the frequent success of the Weir-Mitchell rest cure in metritis we have an example of this relation, in that the local condition is reached through the general organism.

The Foundation of the Feminine Element.—Let us keep in mind, therefore, the open end of the Fallopian tube; the effect of static pressure on cellular vitality; the dangerous zone; the resident germ and the ease with which the womb will furnish the culture medium: also, the relation of reciprocal cause and effect between the local and general system—and we shall have well in hand the foundation of the feminine element in general practice.

Depressed Vitality.—Scrofula, tuberculosis, and general debility come to the male as well as to the female. But even the laity appreciates here the significance of the feminine element. How often do anxious parents, reversing cause and effect, seek advice lest a daughter's amenorrhœa "run into consumption." Now all the masculine disabilities entailed by these troubles oppress equally the female—even the female analogue of tuberculous testes and prostate. She suffers, in addition, the feminine element. There may be amenorrhœa, a premature menopause, leucorrhœa, inguinal adenitis, metritis, salpingitis, and ovaritis. There may even be primary tuberculous infection without preceding lung lesions; there may be secondary metastatic infection: there may be a primary local infection with a pre-existing and predisposing pulmonary involvement. And, finally, consequent upon the general muscular and vital debility, there may ensue our old familiar menace—the debilitated, congested, auto-infecting pelvic condition.

Patients of this class, therefore, who are not abandoned to the Adirondacks or the board of health, demand a local attention. It is not a sound proposition that because a woman has chronic trouble in one portion of her body it is wasting time to interfere with inroads elsewhere.

Minor Disabilities.—Flatulence, constipation, indigestion, hemorrhoids, cardiac palpitations, facial eruptions, and the like are male as well as female woes. Women get them from all the causes that give them to men, plus an additional feminine cause. They entail upon women all that they put upon men, plus the feminine element.

Inflammation in the perineal region of men will inhibit intestinal peristalsis, but this is a brief acute condition and bears little resemblance to that reflex inhibition in the female from a chronic congested or inflamed pelvic condition.

It is necessary only to refer in passing to the nausea of pregnancy: to the piles mechanically produced by the retroverted womb, returning as often as cut and relieved only by the tampon; to the intestinal or nasal hemorrhage due to vicarious menstruation; to the facial acne relieved by vaginal irrigation and tampon; to the cardiac palpitation, left-shoulder and arm cataleptic seizures, due to aggravation of the sexual element, ungratified or overgratified.

Virginity as a Diagnosis.—Virginity, as a diagnosis, will perhaps meet criticism. Yet continuing virginity is an abnormality. The insistence of func-

tion in the human is as sturdy as is the gosling's tendency, even though hatched out by a hen. And what is the physical basis of such functional demand but a vasomotor determination of blood to a part for a purpose? The purpose continuing unfulfilled, repeated blood invasions modify the part. Two seemingly opposite, yet related, conditions follow: infantile uterus and pelvic congestion.

Menstruation a Gift from Civilization.—Civilization has profoundly modified the human female. It is quite possible that menstruation has come to her by evolution, and that in her ancestral state she would conceive at puberty and conceive again at the end of each nursing-period, and so reach the barrenness of age without opportunity for menstruation. But civilization has delayed marriage and pregnancy from year to year until the hereditary line in which function has been starved and delayed has rendered woman especially liable to the malady of infantile uterus.

Infantile Uterus.—Infantile uterus—characterizing a race of young women pubescent but not nubile—develops later in life into the exactly opposite condition of abnormal vascularity and congestion. Less than five years will sometimes change an infantile uterus in an unmarried girl with amenorrhœa into a condition of turgid pelvic congestion yielding profuse menstruation. Lawson Tait has long since pointed out that this atrophied condition leads inevitably to inflammation of the appendages.

Dr. W. Gill Wylie some years ago showed one reason why uterine diseases are more prevalent in America than in Europe, among the rich than among the poor. As the sexual organs of women are the last of her organs to develop—and do develop just at the time when the greatest intellectual efforts are being made—those deficient in vitality suffer the imperfect development. As American women are more active intellectually than their European sisters, as the rich expend greater effort upon mental development than do the poor, it follows that it is among these that infantile uterus and its subsequent involvements are principally to be found.

Leucorrhœa, erosion of the cervix, menstrual irregularity, an unreasoning nervousness and mental depression, and later in life abnormal vascularity and congestion—these are the well-known results of infantile uterus and virginity. When the stage of pelvic congestion is reached we are face to face with our old menace, with its reciprocal relation to the entire organism.

Prevention.—This subject, both in the aspect of prevention and in that of cure, is one of great importance. As the medical man is the sanitarian, and the specialist arrives only when the affliction falls, this subject is one for the general practitioner.

Take these young women upon whom the affliction has fallen to the physician, and he will fail ingloriously in treating them upon the prescription-blank basis. Take them to the surgical gynæcologist, and save for the expedient of dilating the cervix there will be little for him to do; there will be nothing to take out. The malady must be successfully met at the juncture of the specialty and general practice.

Infectious and Contagious Diseases.—In scarlet fever, typhoid, typhus, small-pox, diphtheria, pneumonia, malaria, rheumatism, gout, lead poisoning, and syphilis the female is subject to all the disabilities that fall upon the male, and requires all the remedial measures that the male requires, plus something in addition. That something is the feminine element, and that element, though falling within the range of gynæcology, has as yet been scantily touched.

Medical authors mention casually a uterine involvement in these diseases, but there are few details. Massin has studied their pelvic aspect from the autopsy table, finding parenchymatous and interstitial inflammation, tumefaction of glands, and infiltrated interglandular tissue. That marked uterine involvement does take place in these troubles is not to be disputed. Yet how often is uterine attention made a part of the routine which medical men outline for these diseases?

On the question of typhoid fever in the female I want to speak most warmly, and with the authority of sad experience. There is a direct line of communication between the seat of the typhoid poison and the genital system of women. Clado has demonstrated the existence of direct lymphatic connection between the appendix and the ovary. I have had a patient under my charge with a sinus from the appendix emptying into the bladder.

Syphilis in Women.—Many practitioners have succeeded with syphilis in women without local examination or attention. Many cases have correspondingly small need of throat or nose attention. But it is certain that all cases cannot be properly treated with prescription blank and medicine alone. Local attention is very frequently necessary. Few will dissent from this in cases in which chancres or condylomata are unmistakably present, as, for example, when an ulcer gives a recto-vaginal fistula. The primary lesion of syphilis is comparatively rare in women. Neumann, of Vienna, found only fifty-five initial lesions in eight hundred infected women. Though seeing personally a large number of these cases, the writer has likewise found comparatively few initial lesions. But he has frequently seen profuse condylomata develop a year after infection, from a relaxed vigilance in treatment or from local uncleanliness. This has been followed or at least accompanied by a marked eruptive manifestation on the body. Whether the local lighting up of virulence let a new invasion of poison into the system, or whether the systemic condition allowed the local revival, is debatable. The coincident fact, frequently observed, is simply cited.

In view of the rarity of the initial lesion in infected women, and in view of the almost constant presence of a local vaginal and uterine congestion in these cases, the inference might be drawn that this congested condition often forms the feminine initial lesion, and therefore may be regarded as a primary seat of infection. But this is not exclusively so, for the writer has seen this same local congestion when the initial lesion developed upon a crack on the thumb—the infection occurring in an elderly woman from washing the clothing of an infected daughter, as was clearly traced.

The pathology of this local condition has not yet been exploited, but the writer believes that what Morell Mackenzie says of syphilis of the throat will apply with equal force to the genital system. He says: "In secondary syphilis we sometimes find a very obstinate condition of the laryngeal [one may add vaginal and uterine] mucous membrane, but it is often impossible to tell whether this condition is really due to the specific dyserasia. As I have long pointed out, there is nothing characteristic about the congestion of syphilis." This congestion doubtless yields a mixed infection, the process of which is clear when we remember our resident germ and the culture medium made for it by anything congesting the womb.

Syphilitic Salpingitis.—The profession has no definite observations on syphilitic salpingitis. Theoretically we can explain such a salpingitis from this resident germ, the succulent uterus of congestion, and the extension to the tubes. The metritis resulting from this congestion and the inevitable auto-infection kill the fœtus in syphilitic parents, even when this is not done by distinct syphilitic lesion in the placenta.

Is it not, therefore, safe to say that the physician who treats syphilis in women must go as far into

gynæcology as the gynæcologist must go into the practice of medicine in treating the same condition?

Subinvolution and Superinvolution.—Most midwifery done by professional men falls to the general practitioner. The relation of heart and kidney disease to pregnancy is too wide for more than passing mention.

The post-puerperal treatment of women is, however, to our point. The classic time for making the last visit and collecting the fee is the tenth day. The woman, as a rule, is left to nature from this time on. Considering the post-puerperal engorgement of the womb and the fact that involution is rarely complete before the sixth week, and reflecting upon the gravity of subinvolution in the light of the resident germ, the writer requests the judgment of the profession upon the advisability of establishing a routine of observation of these women from the classic tenth day to the time of complete involution. Meddlesomeness which prevents trouble cannot be logically more reprehensible than is that search of the dentist every six months for a trace of tooth decay.

The Menopause.—The majority of women at the menopause are guarded by the general practitioner. The specialist rarely sees them unless cancer is suspected. Some doctors and most of the laity regard extensive hemorrhage as natural at the "change of life." It is well known that the menopause in married or unmarried women frequently brings a metritis from the intense congestion, analogous to the virginal metritis, and that therefore non-surgical local attention can often palliate much of the disability which is commonly considered natural at this time of a woman's life.

Rheumatism, Gout, Lithæmia, Renal Insufficiency.—That these troubles have an intimate relation with the female pelvic organs—a relation which has no analogue in the male—is being pointed out by one observer after another. A burnt-out muscular product in the pelvic muscular tissues of women with deficient oxidation will frequently simulate pelvic disease.

In a recent paper on "Retrodeviations of the Uterus" the writer dwelt upon the significance of the connection between diseases of this class and pelvic diseases of women, and pointed out how apt are the general conditions to be overlooked, "since these patients, because of the predominant uterine symptoms, are seen only by the gynæcologist during the period when the insidious vital changes can be checked." The reverse condition is likewise true—that the general practitioner often overlooks the local condition in these troubles.

Passive Congestion.—Passive congestion in women can come from all the causes that bring it in the male, plus an additional feminine cause. It entails upon the woman all that it inflicts upon the man, plus an additional feminine disability. As an example of joint male and female causes we can run over the list of table pleasures, alcohol, lack of oxygen, malaria, constipation, anxiety and worry lowering the nervous tone, cardiac lesions, feeble heart, exhausting disease, tumor in the mediastinum or elsewhere. Additional feminine causes comprise excess in venery; plastic exudates and growths in the pelvis; and the comprehensive feminine malady involved in muscular debility, enteroptosis, subinvolution, and retrodeviation. While sexual excess lowers nervous tone in the male and enlarges the prostate, its mechanical results in the female are so much greater that it is entitled to place in the female catalogue. Male and female have jointly entailed upon them by passive congestion the familiar heart, kidney, liver, and gastric changes, which lead along the well-known path to dropsy and the end. But the female has an early and exclusive entailment, namely an aggravation of pelvic congestion, which our resident germ and succulent womb soon transform into a low form of metritis and frequently salpingitis. This reacts upon the system by further retarding an already sluggish stream. It strikingly illustrates the relation of reciprocal cause and effect which the genitals bear to the general system.

Considering the static area occupied by the genital system in the circulation, is it not sound to urge local attention, and must not these troubles be met at the merging-point of the specialty and general practice?

In the Province of the Neurologist.—Passing to the province of the neurologist, and touching neurasthenia, nerve exhaustion, spinal irritability, and epilepsy, here again we have a surplus feminine element of cause and entailment, and an additional line of treatment over what is required for the male. Recall the frequency of floating kidney in female neurasthenia. Recall how infrequently floating kidney is found in the male. Recall the fact that much of what was formerly supposed to be spinal irritability in the female is now known to be floating kidney. There is a strong connection between these debilitated conditions in the female, floating kidney, general enteroptosis, and retrodeviation of the womb. Local attention is frequently urgently required, and the neurologist must trench upon gynæcology.

Take, for example, an exhausted girl with profuse menstruation and a general neuralgic condition. Endless drugging will often fail, while stopping her menstruation by tamponing twice daily during the period will bring up her blood count and yield speedy recovery. In some forms of epilepsy recurring at menstrual periods—whether true or false epilepsy, it matters not—many cases which have resisted a long course of bromides have yielded almost instantly to tampons and purgatives. And this has been marked in cases in which there was nothing more serious locally than a retrodeviation or small ovarian cyst.

The same will hold true in innumerable cases of headache, intercostal and facial neuralgias. The prescription blank cannot cure them; there is no excuse for the knife; and they are successfully treated only at the merging-point between the specialty and general practice. Hysteria and sexual perversions are simply cited in passing.

This paper will serve to open a discussion on the merely physical aspects of the feminine element in general practice. There is a psychical side as interesting, but far less practical. If the writer can stimulate discussion by the fellows of the New York Academy of Medicine on this subject—never yet formulated in type—he will be more than content.

66 West Fiftieth Street.

Hereditary Granular Kidney in Early Childhood.—Hellendall (*Archiv fur Kinderheilkunde*, xxii., p. 61) reports two cases of bilateral chronic interstitial nephritis in children whose mother also suffered from chronic nephritis. The older of the two lived two years, the younger six months. The history of the case points to the fact that the disease of the mother began with the pregnancy of the first child. The degree of contraction, which upon microscopical and macroscopical examination of the kidneys of both children was very intense and marked, leads Hellendall to the conclusion that the development of the contracted kidney began *in utero*. There was no syphilitic history. Bacteria could not be demonstrated. Scarlet fever and other etiological factors were wanting. Thus far but nine cases (including these two) of primary granular kidney have been reported.

THE FIRST COMPLETE REMOVAL OF THE HUMAN STOMACH IN AMERICA; PROBABLY ALSO THE FIRST TOTAL GASTRECTOMY IN THE WORLD. A CONTRIBUTION TO THE HISTORY OF THIS SUBJECT.

By JOHN C. HEMMETER, M.D., Ph.D., Etc.,

CLINICAL PROFESSOR OF MEDICINE AT THE UNIVERSITY OF MARYLAND, BALTIMORE.

In reporting his unique case of complete removal of the stomach—a successful œsophago-enterostomy—Dr. Carl Schlatter, of Zürich, has asserted that all recorded cases of gastric excision are without exception instances of partial, chiefly pyloric, removal of the stomach. In his first publication on this subject, "Ueber Ernährung und Verdauung nach vollständiger Entfernung des Magens — Oesophago-Enterostomie — beim Menschen,"[1] as well as in his second publication, "A Unique Case of Complete Removal of the Stomach, Successful Œsophago-enterostomy; Recovery,"[2] he narrates the case of Langenbuch,[3] in which at least seven-eighths of the stomach ware removed, recovery following.

From a physiological standpoint, this case of Langenbuch can reasonably be regarded as a total extirpation. The case of Professor Schuchardt, of Stettin, in which only a narrow strip of the stomach near the cardia was left in and the entire remaining portion of the stomach excised, can also from a functional standpoint be regarded as a total excision, for none of the gastric motor, secretory, or absorptive functions can be carried out by such a small remnant of the cardia. The execution of these functions depends upon the integrity of the fundus and pyloric end of the stomach. Schuchardt's patient lived two and one-half years after the operation, and apparently enjoyed perfect health during that time. At the International Medical Congress at Moscow, Ewald read a paper on "Erfahrungen über Magenchirurgie, vornehmlich bei malignen Geschwülsten,"[4] in which he referred to an ablation of the human stomach, which Dr. Schlatter characterizes as incomplete because about an inch of the cardiac end had not been excised (the patient died three days after the operation, from hemorrhage).

The hair-splitting distinctions which Schlatter makes between his operation and those of Langenbuch, Schuchardt, and others, are more apparent than real. The questions to be considered in connection with total gastrectomies are, in the first place, in what way can surgical technique be enhanced by such operations? and secondly, what contributions to the physiology of the stomach, of digestion in general, and of metabolism are made possible, after complete gastrectomy, which are not possible by physiological or any other methods? The author is not a surgeon, nor is he able to elucidate from the paper of Schlatter whether he concedes that Krönlein, Langenbuch, Schuchardt, Hacker, and Maydl have performed successful total gastrectomies; but it would appear to him that it is simpler from the standpoint of surgical technique to perform œsophago-enterostomy than to be compelled to leave in a portion of the stomach and perform a gastro-duodenostomy. Perhaps the advance in surgical technique that is gained by Schlatter's successful case is that he has shown a simpler way of union between the œsophagus and jejunum. It may be simpler hereafter to take out the entire stomach and perform an œsophago-enterostomy in preference to leaving in a part of the stomach, even when that is possible. The value of the new operation consists of and is limited to the advance represented by this simplification.

[4] Berliner klinische Wochenschrift, 1897, No. 37, p. 798.

The second possible advantage that medical science might gain from the operation, the contributions in Schlatter's paper to the "Physiology of Digestion in General and of Metabolism," are all confirmatory of studies and operations made previous to his œsophago-enterostomy, and can hardly be considered original. In his most recent paper, "Œsophago-enterostomy after Total Extirpation of the Stomach,"[1] and also in the paper in the *Correspondenzblatt für Schweizer Aerzte*, he gives a detailed and separate description of the effects of loss of each of the separate gastric functions. These are: (1) The action of the stomach as a reservoir by retention of the food—the intestine is thereby protected from being overcharged with a mass of ingesta at a time. The extreme temperatures of ingested food, which would be detrimental to the sensitive intestinal mucosa, are thus corrected. (2) The mechanical function of the stomach, by which the ingesta are gradually mixed with the gastric secretion, thoroughly macerated, reduced to a semiliquid, pulpy mass, and gradually, by complicated peristaltic movements, propelled into the duodenum. (3) The secretory or chemical function which is exerted by the pepsin, HCl, and the rennet ferment, converting proteids into peptones and bringing milk through its preliminary stages of digestion. Fats are not at all digested in the stomach, and amylolysis occurs only as long as the amount of free HCl does not exceed 0.07 per cent. (4) The disinfecting action of the HCl, which has been described by Bunge. This must not be considered as an absolute disinfection. A great many of the more resistant bacteria and the spores of the less resistant pass through the stomach uninjured; the HCl of the stomach has also an inhibitory influence on the fermentative and putrefactive processes of the intestine. This has been demonstrated by A. Ewald, when he showed that the formation of lactic and acetic acids in the intestine was restricted by HCl. The products of proteid decomposition—the phenols, cresol, the indoxyl-sulphuric, cresol-sulphuric, and scatol-sulphuric acids—are excreted in the fæces and in the urine. Charles E. Simon[2] has shown that the indican of the urine is a true index of the amount of putrefaction occurring in the intestine, and that the indican increases when the normal secretion of HCl diminishes. The action of secretion of rennet ferment, which would be lost after a gastrectomy, can be replaced by the milk-curdling substances occurring in the pancreatic juice.[3] (5) The resorptive function, by which peptone, sugars, and alcohol are absorbed from the stomach, is of minor importance from a pathological and physiological standpoint. It appears from von Mering's investigation that water is practically not at all absorbed from the stomach, but that alcohol and whatever is in solution with it is absorbed readily. Grape, milk, and cane sugars, also maltose, are absorbed in moderate amounts, when they are in aqueous solution; but when they are in alcoholic solution larger amounts are absorbed. Dextrin and peptone are taken up from the stomach in smaller amounts than are the sugars. We may then consider the various functions of the stomach appropriately under five headings: 1st, the reservoir action; 2d, the mechanical, motor, or peristaltic function; 3d, the secretory function; 4th, the disinfecting action; 5th, the resorptive function. This is by no means a complete and exhaustive consideration of the gastric functions. The HCl, for instance, in itself acts in six different ways,[4] and the stomach may under certain conditions excrete other products; finally it regulates the amount of chlorides in the body metabolism or at least has a controlling influence in the

[4] See "Diseases of the Stomach," by J. C. Hemmeter, p. 49.

metabolism of chlorides. To our knowledge of the reservoir action, very little has been added by Schlatter's operation, except to confirm the already well-known impression that this action is so indispensable for regulating the temperature of the food and preventing overcharging the intestines with a mass of ingesta, that even when the stomach is removed at a time the part of the intestine which is first reached by the food after it leaves the œsophagus becomes dilated and forms a pouch or receptacle, imitating the reservoir action of the lost stomach.

Loss of the mechanical function has been studied in cases of atony of the stomach; defective peristalsis is the gravest affection that can befall the organ. In its effects it is far more serious than loss of secretion; its loss cannot be replaced, and in Schlatter's case a diet had to be selected which consisted of finely divided food which required no mechanical action for its disintegration. Considering the fact that his patient had only one tooth and that one carious, the good digestion in the complete absence of the stomach must be considered most extraordinary.

The secretory or chemical function, which Schlatter considers the most important of all the gastric functions, is really subsidiary in importance to the motor or mechanical function. Gastro-enterologists have reported many cases of complete absence of gastric secretion,[1] in which metabolism and body weight progressed normally; but no case of loss of motor function is conceivable in which the gastric and intestinal functions could progress normally. All of the chemical functions of the stomach, the partial amylolysis and the proteolysis, can be more effectively carried on in the intestines; all this belongs to a territory which has been well explored and needs no further consideration. The disinfecting action of the gastric juice, although it has been considerably exaggerated, is nevertheless of some protective value. My experience teaches that those persons who have no secretion of gastric juice are more liable to diseases of the stomach and intestines, or, as Lubarsch puts it: "Those who have lost it have one weapon less in the struggle for existence." The resorptive function of the stomach has been very carefully studied by von Mering, Moritz, as well as by Penzold, Faber, Julius Miller, Zweifel,[2] Herschel, and the writer; and nothing new has been added to our knowledge of it by the Schlatter operation. So we feel justified in concluding that the advance gained by the first successful œsophago-enterostomy is limited to the perfection and simplification of surgical technique.

The ingenuity and the diagnostic and surgical ability displayed in this celebrated case cannot but command universal admiration; but we believe its importance has been exaggerated by the lay press, and also by the medical journals, which, like the operator and author himself, are not aware of the fact that it is not the first operation of its kind that has been performed. This error we must also charge to Drs. A. C. Bernays and Hugo Summa, of St. Louis, Mo.[3]

The main object of this communication is to call attention to the fact that the first total ablation or extirpation of the human stomach was executed in America, long before Dr. Schlatter's operation or that by Dr. Bernays in this country.[4] It was executed by Dr. Connor, of Cincinnati, and is reported in the *Centralblatt für Chirurgie*, 1885, p. 549; and 1886, p. 566. It is also referred to by Haberkant in the *Archiv für klinische Chirurgie*, Bd. li., Heft 3, entitled "Ueber die bis jetzt erzielten unmittelbaren und weiteren Erfolge der verschiedenen Operationen am Magen." Connor's operation, it is true, was not a success; he attempted to unite the œsophagus with the duodenum, without attempting an œsophago-enterostomy in the manner that was later on successfully carried out by Schlatter. The patient was a female, fifty years old, and died very soon after the operation.

The patient operated on by Dr. Bernays lived thirty-six hours. The operation of Connor met with severe condemnation at the time, and Haberkant calls it "Eine tollkühne Operation."

It seems that the priority of an operation can be claimed by the surgeon if he was the first one who executed it; the remote results and duration of life after the operation do not come into consideration in this connection. It would be more advantageous to the integrity of American surgery if the remote results were accepted as a test of the success and value of an operation only, and claims to the priority of an operation not made unless the results show that surgical science has benefited by the new procedure. The end object of all science, surgical or medical, is not the development of abstract methods and technique, but to relieve and to cure. It is evident, therefore, on the evidence given from German surgical journals, that the first total extirpation of the human stomach was executed by Connor, of Cincinnati.

Schlatter's operation was performed on September 6, 1897. Assuming that the patient is still living at the present time, she will have survived for six months after the operation. The duration of life after œsophago-enterostomy should in the average be as favorable as after pyloric resection, because the latter is really an equally serious operation. Schlatter does not state how long his operation required, but he remarks that the œsophageal and duodenal clamps when removed had remained in position for "over two hours."[5] Dr. Bernays' operation, which was not an exact imitation of Schlatter's, but rather a repetition of Connor's operation, attempting a union between the pylorus or duodenum and œsophagus, had taken two hours and six minutes. As regards the duration of life after resection of the pylorus, some information can be gained from the following table:

DURATION OF LIFE AFTER RESECTION IN FIFTY-ONE CASES OF CARCINOMA OF THE PYLORUS (Haberkant).

Death.	Number of Cases	Cause of Death.	Living at Date of this Report.	Number of Cases	
After 1½ mos.	1	Return of cancer.	After 2 mos.	1	
" 2 "	3	One of metastasis in the liver.	" 3 "	1	
			" 3½ "	1	
" 2½ "	1	Acute lung disease, no return and no metastasis.	" 4 "	1	
			" 6 "	1	
			" 7½ "	1	
" 4 "	2	Return.	" 8 "	1	
" 5 "	2	One of lobular pneumonia, one of chronic pyemia.	" 9 "	1	
			" 1 yr.	2	
			" 1 yr. and 2 mos.	1	
" 6 "	2	One of return, one of cicatricial stenosis.	After 1½ yrs.	1	
" 6½ "	1	Return.	" 2 "	2	
" 7 "	2		" 2 " and 2 mos.	2	
" 8 "	1	Return.	After 2½ yrs.	1	
" 10 "	1	Return.	" almost 3 yrs.	1	
" 11½ "	1	Rectal and pelvic carcinoma.	After 3½ yrs.	1	
" 1 yr.	3	In two return.	" 5 yrs. and 4 mos.	1	Kocher.
" 13 mos...	2	Return.	Over 8 yrs.....	1	Ratimmow.
" 1¼ yrs.	1	Return.			
" 2½ "	1				
" 3 "	1	Cicatricial stenosis.			
" 5¼ "	1	Not stated (Billroth).	Total.....	21	
Total.....	26				

It will be seen from this table that patients subjected to pyloric resection, from whom considerable portions of the stomach were removed, lived from one to five years, and one patient of Ratimmow lived over eight years and was still alive at the date of Haberkant's report.

The merits of Schlatter's case are, however, already

[5] MEDICAL RECORD, *l. c.*, p. 911.

clearly established; they will improve with every day that the patient lives, but the extraordinary credit of this operation cannot be reduced, even if the case should end at the present moment.

In the *Journal of the American Medical Association* (vol. xxx., No. 10) for March 5, 1898, Dr. J. M. Bayley reports a complete excision of the stomach performed by him on September 29, 1893, for what proved to be a gastric sarcoma involving all but a small portion of the stomach and the mesentery throughout the abdomen. The patient lived only thirty-six hours.

In the New York Medical Record for March 12, 1898, page 380, there is a brief notice, gleaned from the lay press of San Francisco, that a surgeon of that city made a complete excision of the stomach on February 25, 1898, in a female patient suffering from cancer. It is a fortunate thing for the American record of such cases that the patient was reported still alive with normal pulse and temperature thirty-six hours after the operation.

A complete gastrectomy has been performed in Chicago; I have not as yet been able to find it recorded in the medical press, but the patient did not live for thirty-six hours after the operation.

This fatality after complete gastrectomy in this country should bring the aspirants for surgical fame to their senses, and call a halt to further endeavors to imitate Schlatter.

The consummate experience of the cleverest operators and surgical philosophers points unmistakably to the conclusion that in malignant disease of the stomach gastro-enterostomy gives the best results obtainable whenever there are secondary metastases or adhesions. My personal experience confirms this deduction. It is not necessary to give predigested foods, as the intestine is capable of digesting a sufficient amount of food to maintain the nitrogen equilibrium, and in a number of my cases in which I advised my surgical friends to execute a gastro-enterostomy the patients even gained in weight. A case like Schlatter's will probably not occur once in a thousand presented for operation. There were a number of very important factors governing the result of the operation, on which he took his chances. In fact, the patient has as yet not lived long enough to disprove the possible existence of minute metastases, impossible to discover even after laparotomy.

Heart Complications in Diphtheria. — Dr. C. M. Hibbard (*Boston Medical and Surgical Journal*, Nos. 4 and 5, 1898) draws the following conclusions: 1. A rapid pulse rate in diphtheria is to be dreaded. Death usually results when it exceeds 150. 2. A slow pulse —60 in young children—is a sign often of serious heart trouble. 3. Irregularities in the pulse occur in about ten per cent. of the diphtheria cases, and are generally significant of cardiac complications. 4. A systolic murmur at the apex is heard in about one case in ten, and its prognostic value depends upon the nature of the cause. 5. A *bruit de galop* in diphtheria is a most fatal sign. 6. After four weeks, with no heart symptoms in diphtheria, there is little probability of subsequent cardiac trouble in the convalescence. 7. All diphtheria patients who have tachycardia, bradycardia, irregular or weak pulse, a systolic murmur at the apex, vomiting, or any paralysis—especially palatal—should be kept quiet in bed. 8. The most important element in the treatment consists in absolute rest in bed. 9. The vagus nerve in the fatal cases always had some evidence of degenerative changes. The weight of the heart was increased. 10. The cause of death is usually from cardiac thrombi, dilatation, or paralysis, produced most probably by the toxin of the diphtheria bacillus.

Clinical Department.

PUNCTURED WOUND OF THE THORAX, INVOLVING THE PERICARDIUM AND HEART. DEATH SIX DAYS AFTER INJURY. NECROPSY.

By J. C. HILL, M.D.,

ROCKLAND, ME.

Annunziato Nicola, Italian, aged twenty-three, was stabbed in a quarrel July 2, 1893, by a fellow-workman. When first seen by the surgeon, Dr. J. M. Wakefield, eleven hours after the injury, he was bleeding at every inspiration, blood spurting out of the thoracic wound. The pulse was regular, at 90 a minute. He was weak from hemorrhage; the clothing was saturated with blood. A large pool of blood was on the ground by his side, where he had lain all night. He was able to walk on the day following his injury fifty feet or more; he walked a short distance after the injury, as was evident from his distance from the scene of the affray when found. Four days after the injury he was transported a distance of twelve miles in an

ordinary vehicle, and was admitted to the United States Marine Hospital at Rockland, Me.

The victim was confined to his bed a part of the time, but got up occasionally and walked more or less about the ward. The night previous to his demise he was apparently in good health, as was stated to the coroner by the physician in charge. He died suddenly on the morning of the 8th of July.

The following is the record of the autopsy, made six hours after death. Height, five feet seven inches; weight, one hundred and forty-five pounds; rigor mortis present.

Externally.—Wound No. 1. Incised flesh wound through the superficial tissues in the left iliac region, one and one-half inches above the anterior superior spine of the ilium, two inches long; closed by suture.

Wound No. 2. Incised flesh wound through the superficial tissues in the axillary region over the sixth rib, two and one-half inches long; closed by suture.

Wound No. 3. Incised wound in the posterior part of the axillary region, one and one-half inches long, penetrating into the thoracic cavity downward and forward.

Wound No. 4. Incised flesh wound through the muscular tissue in the posterior part of the axillary

region between the sixth and seventh ribs, one and one-half inches long; suppurating slightly.

Wound No. 5. Incised wound over the external angle of the scapula, three-fourths of an inch long, penetrating upward and outward about three inches toward the acromion process.

Wound No. 6. Incised flesh wound, three-fourths of an inch long, one and one-half inches above the left patella.

Wound No. 7. Small puncture over the left trochanter through the skin.

There was an old cicatrix over the dorsal surface of the left foot, three-fourths of an inch long. There were vaccination scars upon either arm.

Internally.—Head: Dura mater normal. The brain was of ordinary size; the external appearance

was normal. The pia mater was easily detached. The tissue was of normal consistence, but somewhat anæmic.

The thoracic cavity contained about three pints of fluid, mostly blood.

Lungs: Right, normal; left, contracted and contained tuberculous nodules. There was an apparent wound downward and forward on the anterior surface of the lower lobe, cutting the pleura and grazing the lung. There was passive congestion of the whole lobe. The fourth rib was slivered along the lower edge at the point of the penetrating wound. A small incised wound was found in the diaphragm very near the median line; non-penetrating.

Heart: Size, four by five inches; enlarged. There were evidences of old pericarditis in some adhesion of the pericardium. There was a penetrating wound through the pericardium into the left ventricle of the heart; no injury to the valves.

Liver: Weight, about five pounds; external appearance normal: on section, evidences of fatty infiltration.

Kidneys: Normal.

The accompanying illustrations show the situation and direction of the wound of the heart.

Anthrax spores have their virulence little, if at all, impaired by drying. Hides infected with the anthrax bacillus are not safe even after soaking in brine or in milk of lime, after undergoing the shaving process before tanning, or after six weeks' treatment in the tanning process.—Griglio, *l' Uffiziale Sanit. e di Chir. Vet.*

Progress of Medical Science.

Local Anæsthesia. — Honigman (*Centralblatt für Chirurgie*, No. 51, 1897) claims that, excellent as is the Schleich infiltration method of anæsthesia, it is in many cases, such as felons and other affections of the fingers and tendons, impracticable. In such cases he strongly recommends the following method of Oberst: The extremity, having been rendered anæmic by elevation, is tightly constricted with an elastic band above the operative field. A quarter to half an hypodermatic needleful of a one-per-cent. cocaine solution is then injected close to the point of constriction and toward the distal end. By this means the anæsthesia is a complete one and remains so as long as the circulation is cut off.

Chronic Vaginal Gonorrhœa.—In a very thorough article, Dr. Bodenstein ("On the Existence and Therapy of Chronic Vaginal Gonorrhœa," *Deutsche medicinische Wochenschrift*, 1897, No. 42) states that primary gonorrhœa of the urethra in women is rare; the primary infection is usually localized in the posterior vaginal vault, the urethra being secondarily infected by the discharge. As a means of microscopically proving hidden cases of gonorrhœa, Bodenstein advises thorough tamponade of the vagina, in both the anterior and posterior fornices, with cotton dipped in a ten-per-cent. ichthyol-glycerin solution. Through the dilatation thus effected and by the hygroscopic properties of the glycerin, the gonococci—which the writer believes are situated in the subepithelial connective tissue—are brought to the surface, and hence may be examined. If in this manner the diagnosis of gonorrhœal infection is made, the ulcerated and at times bleeding spots are touched with a two, five, or ten per cent. argentic-nitrate solution. Strong bleeding may be stopped by tamponade. The most favorable time for this treatment is either shortly before or shortly after menstruation. Cases complicated by subacute inflammation of the adnexa are first to be treated with ichthyol tampons. Bodenstein is of the opinion that the ordinary vaginal irrigation, as practised, cleanses but slightly the posterior vaginal wall. Hence he advises that air be allowed to enter the vagina during irrigation, and more thorough cleansing will result.

The Diazo Reaction in the Urine of the Nursing Child.—Dr. Umikow (*Wratsch*, Nos. 39 and 40, 1897), as the result of many and painstaking examinations, concludes as follows: "The diazo reaction is never found in the urine of the healthy nursing infant. High fever has no effect upon the occurrence of this reaction. The reaction was never found in the urine of infants suffering from acute or chronic catarrhal pneumonia, diphtheria, chicken-pox, otitis media, rhinitis, facial eczema, inflammation of the lymphatic glands, inflammation of the umbilicus, hereditary syphilis, laryngitis, bronchitis, pleuritis, acute catarrh of the small and large intestines, or in erythema caused by the injection of diphtheritic antitoxin. On the other hand, the diazo reaction was always present in erysipelas and measles; the more severe the illness, the more marked was the reaction. In these last-named diseases, as the patients become better the reaction becomes less marked; if these cases go on to a fatal termination, the reaction remains marked till death. In measles the reaction is sometimes found even in the prodromal stage. One or two days before death the diazo reaction is always present in children with any disease: this fact may hence be of prognostic importance."

New York, March 19, 1898.

THE COMMUNICABILITY OF ANIMAL DISEASE TO MAN.

THE fact that many diseases are under certain circumstances communicable from animals to man has now been for some time firmly established. Recent researches have tended further to elucidate the matter, although more conclusive evidence than has as yet been furnished will be required before the premises of some of the investigators will be accepted as finally solving all the doubtful points. The claim advanced by Koch of having established the unity of the tubercle bacillus in all animals has not met with universal credence. Other prominent scientific men hold views at variance with this contention. It has, however, been clearly shown that, given favoring conditions, the flesh of tuberculous cattle is contagious, and that the flesh of tuberculous swine is generally infective, owing to the greater susceptibility of the hog to general tuberculosis. But, putting on one side the probable danger resulting to man from the consumption of flesh infected with the tubercle bacilli, or from drinking the milk of a tuberculous cow, there still remain other bacterial diseases as well as various parasitic complaints which can be communicated by animals to the human being. With the exception of trichinosis and hydatid disease, the majority of these parasitic troubles are not especially dangerous to human life; nevertheless, they are one and all decidedly prejudicial to health, and it is in a high degree desirable that effective means should be taken to prevent their spread. The bureau of animal industry of the United States department of agriculture has just issued a bulletin on the inspection of meat for animal parasites, compiled by Ch. Wardell Stiles, Ph.D., in which the whole subject is treated exhaustively from both a theoretical and practical standpoint. The author states that "this report is primarily intended for the use of meat inspectors, as it is important that they should be well informed in regard to facts relating to the flukes and tapeworms which they are likely to find in the abattoirs and slaughter houses. A knowledge of these worms will enable inspectors to prevent the spread of their tapeworm stage among human beings by condemning the infested meat or subjecting it to processes which will render it harmless. The more important parasites in respect to diseases in man are those of beef measles, pork measles, and hydatids. Hydatid disease is at present comparatively rare in this country, and now is the time to attack it. By proper precautions at the abattoirs and slaughter houses this dangerous parasite can be totally eradicated from the country. If these precautions are not carried out, it will only be a question of time when this country will take its place with Germany and Australia in regard to the number of lives sacrificed to a disease which has not yet gained much ground with us and can now be easily controlled." The preventive measures recommended by Dr. Stiles have already been referred to in a number of the MEDICAL RECORD of a late date. The paragraphs, however, in connection with the disposition of condemned meats are worthy of notice. Three methods in particular are proposed: (1) utilization as a fertilizer; (2) rendering the meats harmless by cold storage, cooking, or preserving, and then placing them on the market; (3) selling the meats under declaration of their character. Of these methods the first, and the most radical one, will commend itself to the judgment of those interested in the health of the people at large. It has the advantage of being an absolutely safe method for the disposition of condemned meat, as there is no parasitic disease known which will withstand the degree of heat used at the large abattoirs in the preparation of fertilizers. In the other two methods the elements of chance enter too largely; probably cold storage if prolonged for a sufficient length of time will effectively answer the purpose, but, on the other hand, if not properly carried out, and particularly with the disease known as pork measles, the parasites of which live for a month or more, there will always be the possibility of spreading infection. These remarks apply with equal force to cooking and salting as a means of destroying certain parasites. As to selling infected meats under declaration, although the custom prevails in certain parts of Europe, it is contrary to all the laws of health and should never be allowed to gain a foothold in this country. In all cases, when meat is condemned by an expert inspector as infected with the parasites of trichinosis or hydatids, it should be subjected to the fertilizer process, and when this method is not available should be consumed by fire. If these diseases are to be stamped out, half-and-half measures will not suffice; they must be eradicated root and branch. Doubtless the few will suffer in pocket, but it will be for the lasting good of the many.

Carter and Horsley.—Mr. Brudenell Carter and Mr. Victor Horsley have been indulging lately in a lively exchange of epithets in the English medical journals, *à propos* of "medical reform," but seemingly neither has paused to consider the advisability of personal reform. The letters which these two individuals have been writing to each other in the columns of the medical press are so full of what the under dog in the fight calls "foul abuse" that legal steps have been threatened by Mr. Horsley to seal his opponent's mouth, or, rather, inkstand.

INFLUENCE OF THE PROFESSOR IN THE STRUGGLES OF THE PRACTITIONER.

In looking about for somebody or something to blame for the hard times, the unprecedented healthiness of the community, the falling off in practice, collections, and everything pertaining to existence except the expenses, the eye of the doctor has not seemed to fall upon the professor. Of course every one knows that there are professors and professors. Some are innocent. Some have had their greatness thrust upon them, and shrink from public gaze. These are for the most part those who actually profess without professing too much to profess. Their names are not seen in the lists of heavy contributors to hospitals and medical schools, nor are they put down as owners of shares in the corporations whose chairs they occupy. They do not feel so puffed up by their titles and so secure in their positions that they can ignore the rights of their fellows, and, indeed, their very nature would not permit them to assume that antagonistic relation to the men in the ranks which is held by others whose constant acts express the sentiment, "The medical public be d—d." They are the men who favor a decrease in dispensary and hospital abuses of charity, and a cessation of miscarriage of the benevolent intentions of dead philanthropists. These men are never heard to say: "I must have patients for my clinics, no matter from what walks they are drawn and no matter what little doctor around the corner whose rent is due is hurt by it."

It is the professor who professes such sentiments as the above who is responsible in a great measure for the "little doctors" who go wrong. After he has paid his fees for four years, helping to support these men and their institutions of learning, the doctor feels that he should be permitted to earn enough to pay his rent, and when he finds his efforts antagonized it is not so surprising that he falls a victim to the alluring fees to be had for intervening to keep down the population. There would be fewer "legitimate" abortionists, fewer "regularly graduated" advertising quacks, fewer disreputable doctors, if professors did their full duty and stood for the profession instead of standing for themselves.

And still it all comes back to the old story of the fault being in the ranks. The doctors could regulate the matter if they would. The professor has to depend upon the men for consultations; his sentiments are known, or can be readily ascertained, and if he finds support of the rank and file withdrawn he must of necessity reform. In self-defence the practitioner should carefully consider the question: "Is the consultant to whom I send my cases for us or against us?"

There is another kind of "professor" who should not be tolerated. He comes from abroad and sends out his cards: "Professor So-and-So, Graduate of Paris or Berlin. Electrical Treatment and Massage." He is willing to take cases sent by a doctor, or will treat any one who applies directly. Though not a medical man, he practises medicine, and we permit him to do so. Every patient he secures is at the expense of some legally qualified practitioner, who has a right to expect protection from this sort of competition. Still medical men will, out of the kindness of their hearts or unthinkingly, support these men who call themselves professors and lose no opportunity to build up paying practices for themselves, independent of the support of the medical profession.

PHYSICAL TRAINING IN PUBLIC SCHOOLS.

The care of the body has been, up to comparatively recent years, strangely neglected in the public schools of this country. It has been considered a quite sufficient educational training for the young to cram and overload their brains with a quantity of matter difficult to digest, and in too many instances even when assimilated of little use in after-life. Numbers of delicate, highly strung children have broken down under the strain, and the dreary daily grind of the monotonous cramming system, undergone in unhealthy surroundings, has developed many of the nervous diseases to which the present generation is so peculiarly susceptible. What does knowledge profit a man, if in the gaining of it he loses the still more precious gift of good health? The nations of the old world, notably Greece and Rome, understood and appreciated much more clearly than do the people of these times the harmfulness of unduly forcing the mind to the lasting hurt of the body. The gymnasiums of ancient Greece probably reached, in their methods of training the young, a higher ideal than have any of the educational systems now in vogue. In the face of this condition of affairs, it is pleasing to note that the people of America are rapidly becoming alive to the pernicious effects of developing the mind at the expense of the body. The more rational mode of educating the young would appear to be that of so training the body and mind that both advance as far as possible at an equal rate. Thus if a child is of weak constitution but possessed of unusual mental capacity, it should be the aim of his teacher to strengthen his physical powers, and until that object is accomplished to let the mind take care of itself; on the other hand, if the reverse is the case, to adopt contrary methods. The individuals should be studied separately, and children should not be lumped together in a body and put through the same course without regard to their different temperaments, dispositions, and constitutions. It is now about ten years since German gymnastics were introduced into public schools of this country; since then physical training has held a place in the curriculum of almost all the large cities of the East. The report of the director of physical training in public schools of Washington has lately been published. According to this report the beneficial results of systematic daily exercise have been marked; but, as the writer of the paper truly remarks: "It is impossible to test the full measure of success or failure of our efforts. It is in the remote future, with school days long past, that the lasting influence of such work will be felt by the individual child." However, one thing seems certain, viz., that the introduction of physical training into the public schools of America is a step in the right direc-

tion, and if intelligently carried out should result in producing a stronger race mentally and physically. The fact should not be forgotten, though, that physical training may be abused. Gymnastics should not be permitted to take the place of play, but rather the two should go hand in hand.

BABY INCUBATORS IN ENGLAND.

Incubators for weakly or prematurely born infants have been introduced into England for rather more than a year, but, over and above the reputation already gained for them by their demonstrated usefulness in preserving infant life, they have also become a quite popular adjunct of an up-to-date show. At Earl's Court, Kensington, an exhibition of incubators was first held on a large scale, and so attractive did they prove as a spectacle that many other places of public entertainment have followed suit and have utilized the idea as a means of turning an honest penny. One of the most popular of the "side shows" at Barnum and Bailey's show at the Olympia is the baby-incubating department.

The principle of incubation dates from very far back. The ancient Egyptians, who certainly used the method for rearing sickly birds, are believed to have been accustomed to apply the system to feeble children. However, in the case of infants, incubating fell into disuse, and it was not until about sixty years ago that Dr. Credé, of the University of Leipsic, invented an incubator of the modern type. He constructed a sort of box with double metallic sides; the space between these walls could be filled with hot water, so as to maintain the desired temperature within the box. In 1878 Dr. Tarnier, when visiting the artificial "couveuses" installed by M. Odile Martin at the Jardin d'Acclimatation in Paris for the rearing of poultry, thought that he might make use of a similar apparatus in the case of prematurely born children. M. Odile Martin was requested to construct a "couveuse" sufficiently ventilated and large enough to hold one or two infants. These were accordingly made, and are said to have fulfilled their purpose in a satisfactory manner. Further improvements have been recently effected, and the incubators at present being exhibited in England are far more elaborate contrivances than their German and French prototypes, and are thus described in *The Lancet* of a few months ago: "The incubator works automatically; both ventilation and heat are maintained without any fluctuations whatsoever, not only for hours, but even for days. It need not be touched for these purposes, and the only attendance necessary is that needed for feeding and washing the infant. The heating is produced by hot water, which circulates in copper piping placed at the bottom of the incubator under the cradle or hammock. This pipe is fed by a water boiler, which stands outside the incubator and may be heated by an oil lamp, by gas, or by electricity. The temperature is automatically maintained at the required heat by a specially constructed thermostat. . . . Thus, whatever changes may occur outside the incubator, the temperature within regulates itself. The ventilation is also automatic. The incubator is made of glass and metal, and therefore can be easily washed and disinfected. It can be readily carried about and used in hospitals and private houses. As yet, owing to their great cost, they are available only for the rich. In London and other large centres incubator stations will be established. In response to a message or telegram, incubators will be dispatched immediately wherever required."

While fully recognizing their merits as a means of preserving the lives of feeble infants, *The Lancet*, in a late number, passes severe strictures on the custom now prevalent in London of making a commercial speculation of incubators, and says, in reference to their exhibition at Barnum and Bailey's show: "What connection is there between the serious matter of saving human life, and the bearded woman, the dog-faced man, the elephants, the performing horses, and pigs, and the clowns, and acrobats that constitute the chief attraction to Olympia?"

News of the Week.

A Physician Arrested for Alleged Carelessness.—A physician of this city was arrested last Saturday on a charge of manslaughter in the second degree, in causing the death of a six-weeks'-old child by the administration of a mixture containing salol and paregoric, and one containing resorcin. The child died on April 13, 1897, and the mother, brooding over her loss, became finally so firmly convinced that the physician's negligence was responsible for its death that she has since then collected evidence which was finally submitted some weeks ago to the district attorney. The gentleman who has met with this misfortune is well known to many of the profession in this city as an able and careful physician, and we trust, and doubt not, that he can fully establish his innocence of any culpability in the matter.

Naval Surgeons Wanted.—In consequence of the humiliating treatment to which assistant surgeons are subjected on entering the service, the navy finds itself short of surgeons at a critical time. The surgeon-general has therefore recommended that authority be granted immediately for enlisting acting assistant surgeons for ships to be placed in service and on auxiliary cruisers that may be impressed by the government. There are already eighteen vacancies in the lower grade of the medical corps, and in the event of war the medical department would be seriously crippled. Even now there are not sufficient medical officers of the lower grades to meet the requirements of the navy, and the surgeon-general recommends that the obnoxious regulations which have rendered the service so unpopular be removed and at the same time that he be authorized to enlist any number of acting assistant surgeons deemed necessary.

The Health Board.—In New York paternalism runs rampant, and the health office, in its desire to be paternal, manufactures serum for the rich and for the poor, the only difference being that the rich pay for

it. We doubt very much if the health authorities have any more right to produce antitoxin than to manufacture quinine. Would anybody tolerate a board of charities that would start a shoe factory and furnish shoes free to the poor and at cost to the rich?—*The National Medical Review.*

The New York Hospital Medical Library.—By direction of the board of governors, the library of the New York Hospital has been closed and the books have been transferred to the New York Academy of Medicine. It is reported that an attempt will be made, when the new public library is opened, to incorporate with it the library of the Academy of Medicine, all the books and journals in the latter being transferred to the new library building. Were such a move made we venture to predict that the falling off in membership in the academy would astonish the leaders in that scientific organization.

National Quarantine.—It has always seemed to us that government control of coast quarantine is the only feasible and truly efficacious means by which complete protection from invasion of foreign-born epidemic disease is to be obtained, and the logical hands into which quarantine control should be placed are those of the Marine Hospital service, most of whose officers are already well trained in sanitary medicine, and which service has the means and could obtain the authority for the thorough enforcement of international quarantine laws.—*Memphis Medical Monthly.*

Obituary Note.—Dr. William P. Morrissy, of Brooklyn, died at his home in that borough, on March 13th. He was born in Canada, fifty-two years ago, and was a graduate of the University Medical College in this city in 1869. He was for many years a police surgeon in Brooklyn.

The Atlantic County (N. J.) Medical Society.—The following officers were elected at the annual meeting of this society: *President*, Dr. W. Blair Stewart, Atlantic City; *Vice-President*, Dr. H. C. James, May's Landing; *Secretary and Treasurer*, Dr. Walter Reynolds, Atlantic City; *Reporter*, Dr. W. E. Darnall, Atlantic City; *Permanent Delegate to State Society*, Dr. Theophilus Boysen, Egg Harbor City.

The Kings County (Washington) Medical Society.—At the annual meeting of the Kings County (Washington) Medical Society, held in Seattle on January 17th, the following officers were elected for the ensuing year: *President*, Dr. Clarence A. Smith; *Vice-President*, Dr. David A. Mitchell; *Secretary*, Dr. William L. Ludlow; *Treasurer*, Dr. William A. Shannon. The regular meetings of the society are held on the third Monday evenings of each month.

The Mortality Statistics of Philadelphia.—According to the mortality statistics of the Philadelphia board of health, the death rate of that city for 1897 was the lowest for the past thirteen years, being 18.72 per 1,000, based on a population of 1,214,256. Of the deaths, pneumonia leads (as it did in 1896) with 2,723; tuberculosis comes next, with 2,388; diphtheria, 1,474; typhoid fever, 401; and scarlet fever, 282.

Florida Medical Association.—The annual meeting of this society will be held at Jacksonville on April 26, 1898. The president of the association is Dr. R. B. Burroughs, the secretary Dr. J. D. Fernandez.

The Atlantic City (N. J.) Academy of Medicine.—At the annual meeting of this society, held February 14, 1898, the following were elected officers: *President*, Dr. William Pollard; *Vice-President*, Dr. W. B. Stewart; *Secretary*, Dr. E. C. Chew; *Corresponding Secretary*, Dr. William Edgar Darnall.

Johns Hopkins Hospital.—The plans for a new medical building at the Johns Hopkins Hospital have been completed. This will give place for the removal of the physiological and chemical laboratories from the university to the hospital grounds. One floor of the new building will be devoted to pharmacology.

Trained Nurses' Educational Exhibit.—There will be a trained nurses' educational exhibit at the International Health Exposition, to be held next May in this city. The latest medical and surgical appliances will be shown, in contrast with the obsolete instruments of the past; there will be a model operating-room, an ideal nursery, a babies' ward and hospital playroom for convalescent children, orthopædic and ophthalmic rooms, diet kitchen, and a model suite of living-rooms for nurses. The methods of district nursing and first aid to the injured will be illustrated. The department of military hygiene will be specially interesting, showing ancient and modern ambulances and hospital field tents, as formerly and as now arranged. Among the institutions represented will be the training-schools connected with the New York, Presbyterian, Bellevue, St. Luke's, and Mount Sinai hospitals; together with their alumnæ associations, the Post-Graduate School, and the Nurses' Settlement. It is expected that the large training-schools in other cities in this country and abroad will also be represented. Miss Mary E. Wadley, of the Bellevue School, is manager of the nurses' exhibit.

Health Appointments in Baltimore.—The mayor of Baltimore has appointed Dr. C. Hampson Jones as health commissioner in the place of Dr. James F. McShane, and Dr. G. Lane Taneyhill as quarantine physician in the place of Dr. Sydney O. Heiskell. Dr. McShane is a great loss to the health department, having been connected with it for twenty years.

Medico-Surgical Officers.—At the annual meeting of the New York Medico-Surgical Society, held March 7, 1898, the following officers were elected for the ensuing year: *President*, Dr. J. Blake White; *Vice-President*, Dr. William H. Porter; *Secretary*, Dr. Augustus E. Bieser; *Treasurer*, Dr. Frank Van Fleet; *Member of Executive Committee*, Dr. Edward J. Bermingham.

Typhoid Fever is raging epidemically in Budapest, and the Hungarian minister of the interior has appointed a commission to investigate the condition of the water supply and to study into the cause of the present outbreak.

The Association of American Anatomists.—The annual meeting of this association was held at Ithaca, N. Y., on December 28, 29, and 30, 1897, at which time the following officers were elected for the ensuing term: Dr. B. G. Wilder, Ithaca, N. Y., *President;* Dr. George A. Piersol, Philadelphia, *First Vice-President;* Dr. William Keiller, Galveston, Tex., *Second Vice-President;* Dr. D. S. Lamb, Washington, D. C., *Secretary and Treasurer.* Dr. F. J. Brockway, of New York City, was chosen as delegate, and Dr. R. W. Shufeldt, of Washington, as alternate to the executive committee of the Congress of American Physicians and Surgeons; Dr. F. J. Shepherd, of Montreal, Canada, was elected a member of the executive committee of the association, in place of Dr. Huntington, term expired. The following anatomists of the old world were elected honorary members: Dr. Mathias Duval, Paris; Dr. Carl Gegenbaur, Heidelberg; Dr. Wilhelm His, Leipzig ; Dr. Albert von Kölliker, Würzburg; Dr. Alexander Macalister, Cambridge; Dr. L. Ranvier, Paris. It is understood that the next meeting will be held in New York City, in the Christmas holidays, in conjunction with the Society of Naturalists and other affiliated societies.

Ready for Service.—The graduating class of the medical department of Baltimore University, numbering more than one hundred young physicians and surgeons, has passed resolutions offering the service of all the members to the government in case of war with Spain.

"O Brazil Medico," our esteemed contemporary of Rio de Janeiro, edited by Dr. A. A. de Azevedo Sodré, celebrates in its issue of January 1st the completion of its eleventh year. This journal has well merited its success, for its contributors are the leaders in the Brazilian profession and their articles are most valuable additions to the literature of tropical pathology.

Vital Statistics of Philadelphia.—For the week ending February 26th there was a decrease of 15 in the number of new cases of typhoid fever over the same period for last week. While there was a decrease in the number of new cases, there also was an increase of 4 deaths, making a total of 21 deaths for the week. The total number of deaths was 468, pneumonia again leading with 65 deaths against 65 for the previous week. The principal causes of death were: Apoplexy, 23; nephritis, 24; casualties, 12; tuberculosis, 51; diphtheria, 17; heart disease, 36; inflammation of brain, 11; inflammation of bronchi, 12; inflammation of stomach and bowels, 16; measles, 17; old age, 17; paralysis, 12. There was a decrease of 86 over the same period of last year.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending March 12, 1898. Surgeon L. B. Baldwin detached from the *Puritan*, March 17th, and ordered home with two months' leave. Surgeon J. D. Gatewood detached from duty at the Naval Museum of Hygiene, Washington, D. C., March 15th, and ordered to the *Puritan*, March 17th. Assistant Surgeon C. D. Kindleberger detached from the *Olympia*, and ordered home with two months' leave. Surgeon N. H. Drake detached from duty with the *Minneapolis* and *Columbia* and ordered to the *Minneapolis*, March 15th. Surgeon C. G. Herndon ordered to the *Columbia*, March 15th.

The Cuvier Prize of the Academy of Sciences, Paris, 1,500 francs in value, has been awarded to Professor Marsh, of Yale University. This prize is awarded every three years for the most noteworthy work published during that period on geology or zoölogy.

Decrease of Typhoid Fever in Philadelphia.—The severe epidemic of typhoid fever which has existed in Philadelphia for the past two months shows some signs of abatement, there having been 156 new cases with 17 deaths during the week, as against 185 new cases and 21 deaths for the previous week.

Dr. R. Harvey Reed, who recently removed from Columbus, Ohio, to Rock Springs, Wyo., has been appointed surgeon-general of the national guard of Wyoming, with the rank of colonel.

A New International Quarterly.—The *Illustrirte Rundschau*, edited by Dr. Gustav Beck and published by Wyss, of Berne, has just appeared. It is modelled after the *Monatschrift der ärztlichen Polytechnik*, but is rather more pretentious. A fair proportion of illustrations of new appliances in the first number is taken from American literature.

Obituary.

SIR RICHARD QUAIN, BART.,

LONDON.

Sir Richard Quain, M.D., F.R.C.P. Lond., F.R.C.P. I., died in London on March 13th, after a long illness. He was born in Mallow, Ireland, in October, 1816, and began professional life as clerk to an apothecary in Limerick. He afterward went to London to study, and obtained the degree of M.D. from University College in 1842. He served as house surgeon and later as house physician in the University College Hospital, and shortly after graduation was made a fellow of the college. In 1851 he was chosen a fellow of the Royal College of Physicians, and in 1860 was appointed a member of the senate of the university. In 1887, the year the British Medical Association held its annual meeting in Dublin, he was made honorary M.D. by the Royal University of Ireland and also honorary fellow of the Royal College of Physicians in Ireland, and in 1890 received the honorary M.D. degree from the University of Dublin. He was for a long time chairman of the pharmacopœia committee and consequently had much to do with the publication of the last two editions of the British Pharmacopœia. For many years he was physician to the Hospital for Diseases of the Chest at Brompton, and had also been for a long period physician to the Queen. He was the author of many medical writings and was editor of "A Dictionary of Medicine," the first edition of which was published in 1882. It was chiefly as editor of this work that he became known to most of the profession in this country.

Reviews and Notices.

THE DIAGNOSTIC VALUE OF ABNORMAL REACTIONS OF MUSCLES AND NERVES (Bulletin Officiel de la Société Française d'Électrothérapie). By PROF. E. DOUMER, Lille, France.

THE author maintains that the muscular fibre cannot be excited with the electric current alone, save in very exceptional cases. In the majority of cases, the muscular reactions obtained by the application of the electric current at the motor points are due chiefly to an excitation of the terminal filaments of the motor nerves. The term exploration of the muscles, so often employed in electro-diagnostics, is therefore entirely improper.

The author then proceeds to study how excitation of the nerve produces contraction of the muscle, and he shows that the stimulus is transformed into nerve waves at the point of application and thus acts on the muscle.

After having established that most abnormal reactions heretofore described (reaction of degeneration, of compression, of contracture, myotonic reaction) are in reality complicated electrical phenomena consisting of more or less numerous elementary reactions, he proceeds to study the latter, and arrives at the following very important conclusions:

1. Diminished faradic irritability, which he proposes to designate as the reaction of Duchenne, may depend on an alteration of the reacting organ (the muscle) as well as of the excited organ (the nerve); it always points to a lesion in the neuro-muscular system situated below or at the level of the point of excitation.

2. Diminished galvanic irritability justifies the same conclusions, *i.e.*, it likewise points to a lesion in the neuro-muscular system situated below or, more frequently, at the level of the point of excitation.

3. Among the qualitative changes of the galvanic reactions the author studies more especially those variations for which he proposes the term reaction of Erb. He shows that this reaction of Erb always corresponds to a more or less profound lesion of the peripheral motor neurons at the point of excitation. It is entirely independent of lesions situated above or below that point.

4. The other abnormal elementary reactions are too little known yet to serve as a basis for clinical indications.

5. It is necessary to adopt such methods of exploration in electro-diagnostics as allow us to recognize exactly the distinctive character of the excitation and the seat of the lesion.

The writer believes that the elements necessary for the institution of such methods could be found in the remarkable work of Professor d'Arsonval.

TEXT-BOOK OF MATERIA MEDICA FOR NURSES. Compiled by LAVINIA L. DOCK. Third Edition, Revised and Enlarged. G. P. Putnam's Sons. 1897.

THIS little book is designed to teach materia medica from the nurse's standpoint. The outlines followed are those usually pursued in our training-schools for nurses. It is neatly printed and clearly written.

A QUIZ MANUAL OF HISTOLOGY, GENERAL AND DENTAL. By CHARLES B. REED, M.D., and FREDERICK B. NOYES. Chicago: The W. T. Keener Company. 1897.

A SERIES of questions and answers designed for the use of students and beginners in medicine and dentistry has been arranged. The book contains about two hundred pages.

PSILOSIS OR "SPRUE": ITS NATURE AND TREATMENT. With Observations on Various Forms of Diarrhœa acquired in the Tropics. By GEORGE THIN, M.D. Second and Enlarged Edition. London: J. and A. Churchill. Philadelphia: P. Blackiston, Son & Co.

TO a physician practising in the South, or to a physician having to meet rare diseases of the tropics, this will prove a very serviceable work. In it the author presents an excellent monograph on the disease, giving its history, geographical distribution, symptoms, pathology, and methods of treatment. The opinions of other writers are carefully considered, and the work as a whole forms a very complete study of the subject. The book is well illustrated.

SPINAL CARIES: SPONDYLITIS, OR POTT'S DISEASE OF THE SPINAL COLUMN. By NOBLE SMITH, F.R.C.S. Second Edition. London: Smith, Elder & Co. 1897.

WHOEVER wishes to learn something concerning the above disease should read this concise book. The chapter on obscure cases and the one on laminectomy are extremely interesting.

TRANSACTIONS OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION FOR THE YEAR 1897. Volume XIII. Philadelphia. 1897.

THIS volume contains in detail all the papers read by the various authors and the discussions thereon. The association may well feel proud of the contents of this volume, for the subjects are of a high scientific standing.

THE PERITONEUM. By BYRON ROBINSON, B.S., M.D., Author of "Practical Intestinal Surgery," "Landmarks in Gynæcology," and Life-Sized Chart of the Sympathetic Nervous System. Chicago: C. V. Waite & Co. 1897.

THE present volume contains a full and exhaustive description of the physiology and histology of the peritoneum. We are somewhat at a loss to account for the *raison d'être* of such a large book, four hundred pages, on a subject which could have been treated more succinctly and with greater definiteness in much less space, and which would have saved the practising surgeon much time if it were more concise.

For the research student, however, there are many facts which will be of interest. The wealth of matter in the bibliographical index will be a valuable aid to the specialist, as practically everything bearing on the peritoneum is mentioned.

A MANUAL OF PATHOLOGY. Including Bacteriology, the Technic of Post-Mortems and Methods of Pathological Research. By W. M. LATE CORLIN, Professor of Pathology and Bacteriology in Jefferson Medical College, Pathologist to Jefferson Medical College Hospital, and to the Philadelphia (Blockly) Hospital, Bacteriologist to the Pennsylvania State Board of Health. Being a Second Edition of the author's "Lectures in Pathology," Rewritten and Enlarged, with 268 Illustrations. Philadelphia: P. Blakiston, Son & Co. 1897.

THERE is a large number of practising physicians who, for one reason or another, have never enjoyed the privileges of a laboratory course in technical microscopy. To those who are desirous of obtaining the rudiments of such work and to students of medicine this volume is to be commended. A great many facts are here presented in a clear, concise manner, and from a practical point of view. The many illustrations aid materially in the interpretation of the text, although some are too small to be characteristic. The questions at the end of each chapter will probably be of service to the students who attend Professor Coplin's lectures, but to the outside reader they form a detraction rather than a desirable feature.

ATLAS OF CLINICAL MEDICINE. In Three Volumes. By BYROM BRAMWELL, M.D., F.R.C.P. Ed., F.R.S. Ed., Assistant Physician to the Royal Infirmary, Edinburgh. Quarto, three volumes. T. A. Constable & Co. 1897.

THIS work was commenced six years ago, having been issued in parts at stated intervals, and now appears in its complete form, comprising three quarto volumes, elegantly illustrated. As the different fasciculi appeared, we took occasion to comment upon their respective excellences, both as to the admirable descriptive style of the text and the accuracy, truthfulness, and high artistic merit of the illustrations. Regarding the latter, various forms of art have been called into requisition, as photogravure, chromo-lithography, tinted crayon, and simple black and white, demonstrating what can be done in the several lines of work in the way of accomplished perfection in the accurate delineation of complex diseased conditions. The letterpress, which is arranged in double columns, contains a detailed clinical account of the grouped diseases, with minute descriptions of the plates and drawings, thus bringing in a strikingly realistic way the patient and reader in direct contact with each other. Thus, in a thoroughly practical way, the student has a leading, characteristic, or rare case constantly before him for refer-

ence, comparison, and study, which could not be obtained more effectively by any other means.

The selection of the subjects is eminently judicious, and especially appeals to the needs of the advanced student whose purpose is to obtain broader views and more facts concerning many of the recent investigations which have made their impress upon the progressive clinical methods of the period. In fact, the work as a whole is one of the most important ones which have recently appeared in the adaptation of a means to the end of acquiring a liberal medical education in comparatively new fields of study.

The better way, however, to appreciate the purpose, scope, and practical utility of this admirable work is to enumerate in a cursory way the topics that are more or less exhaustively treated in the three large double-columned quartos which complete the series:

Volume I. contains chapters on myxœdema, sporadic cretinism, Friedreich's ataxia, Addison's disease, melanotic sarcoma, Hodgkin's disease, unilateral atrophy of the face, chronic progressive bulbar paralysis, paralysis of the tongue and lips, ophthalmoplegia, molluscum fibrosum, xeroderma pigmentosum, small-pox, globulinuria, chronic insanity, and hilarious insanity.

Volume II. discusses scrofula, unilateral hypertrophy of the skull, measles, Friedreich's ataxia, with knee jerks retained, and with main-en-Griffe; clinical significance of alterations of visual fields, such as hemianopsia, bilateral, partial, permanent, and temporary, and contraction of the field of vision due to lead poisoning; syphilis, Asiatic cholera, anticholeraic inoculation, exophthalmic goitre, acromegaly, general exfoliative epidemic dermatitis, and unilateral hypertrophy of the face.

Volume III. contains communications on the thyroid treatment of skin diseases, poliomyelitis anterior acuta, remarkable cases of cancer of the breasts, spleen, and other organs, congenital syphilis, progressive muscular atrophy, progressive muscular dystrophies, clinical points in cases of pseudo-hypertrophic paralysis, and other forms of progressive muscular dystrophy, cyanosis and congenital heart disease, calcareous degeneration of the heart and other organs, chlorosis, pernicious anæmia, and alopecia areata.

In a word, then, the talented and painstaking author has amply fulfilled his promise in giving to his readers an illustrated treatise on clinical and systematic medicine. It deserves the recognition of every medical scholar who has a wide mental horizon and who wishes to keep well in touch with modern medical thought.

Clinical Methods. A Guide to the Practical Study of Medicine. By Robert Hutchison, M.D., M.R.C.P., Demonstrator in Physiology, London Hospital Medical College, and Harry Rainy, M.A., F.R.C.P. Ed., F.R.S.E., University Tutor in Clinical Medicine, Royal Infirmary, Edinburgh. Philadelphia: Lea Brothers & Co. 1897.

This is an excellent small manual for the technical investigation of disease, of service both to the student and to the busy practitioner. The different chapters embrace the entire category of observable regions and discuss the general methods of examination clearly and concisely. But few interpretations are given, the how rather than the why being the motto of the book.

The chapters on the urine, the blood, and the nervous system, especially the last, are to be commended in particular. The work is well written, and is worthy a place by the side of Vierordt's, Hare's, Von Jacksch's, and Semon's well-known volumes covering much the same fields.

Surgical Pathology and its Principles. By J. Jackson Clarke, M.B. Lond., F.R.C.S., Assistant Surgeon at the North West London and City Orthopædic Hospitals; Late Senior Demonstrator of Anatomy; Demonstrator of Bacteriology, and Curator of the Museum in St. Mary's Hospital Medical School, and Pathologist to St. Mary's Hospital. London, New York, Bombay: Longmans, Green & Co. 1897.

In the present volume the author considers the word pathology in its broadest sense, and treats of the pathological histology and pathological anatomy of most of the diseases of the body for the relief of which operative surgery is usually employed.

This method of interpretation forbids a full treatment, and therefore the different chapters present, in many cases at least, hardly more than an outline of the conditions. The work is an excellent one for students, but is not so complete along its own lines as are many of our American text-books on surgery.

The Psychical Correlation of Religious Emotion and Sexual Desire. By James Weir, Jr., M.D. Louisville, Ky. 1897.

This collection of essays touches lightly upon a very interesting subject, and one that has received much attention from students, viz., the forms of nervous diseases in which religious and sexual manias are allied. The author gives a short historical epitome of certain religions in which phallus worship was prominent, and has collected in a readable form a few of the data given by Spencer and others. He discusses various modern forms of degeneration that are of the same eroto-religious type as were those which passed for some forms of Oriental worship or sanctity in the middle ages. It is an entertaining little book which in no way taxes the mind of the medical man wearied in his endeavors to keep pace with the scientific literature on this subject.

The Trained Nurses' Directory. Compiled and Edited by M. Louise Longeway. Published annually in November.

This will be found a useful and convenient handbook for physicians, containing as it does a very desirable list of carefully selected names.

Vade Mecum of Ophthalmological Therapeutics. By Dr. Landolt and Dr. Gygax. Philadelphia: J. B. Lippincott Company. 1898.

For so small a book many subjects are touched upon (three hundred and twenty-six), some more useful and more practical than others—thus, No. 315, "trional," with its dose, without indication as to what eye affection it is to be employed in. There are too many unnecessary cross-references; the space could have been better utilized. The value might have readily been increased by going more fully into some of the important topics and using smaller type for headings to keep within bounds of space.

Manual of Mental Science. By J. A. Fowler.

This most interesting volume is from the pen of J. A. Fowler, of phrenological fame. Its purpose is a free use in the schoolroom to impress on the mind of the child that he has bumps of localized genius, varying from three to seven, whose exact nature can be diagnosed only by the authoress or one of her persuasion.

A gentle didactic method is used in the first chapters to familiarize the children with the lobes, fissures, and nerves of the brain. For instance, the imaginary Harry steps promptly to the board and writes down all the convolutions, including the gyrus fornicatus, the hippocampal and paracentral lobules, in a manner that might well put to shame any graduate of medicine of a year's standing; while Alfred locates the pons Varolii, the crura cerebri, and the interpeduncular space with an ease that would be envied by a candidate for an M.D. degree.

The lesson on temperaments impresses the fact that the Jew has one of a bilious nature, the German is sanguine-vital but slow, and the American has a mental-motive tendency. But the major part of the book is occupied in pointing out to children the locality of their regions of alimentiveness, combativeness, and philoprogenitiveness, etc. To aid in this, there is a number of illustrations taken from the gallery of a children's photographer, such as are commonly used to advertise the merits of some infant food, but which are here carefully selected to illustrate certain marked traits of character. For instance, a beautiful infant of nine months bears on his hairless crown a small star that indicates a large development of conscientiousness. A similar mark on the curls of a three-year-old who illustrates "sublimity" indicates a large development of the brain that will make him an orator. A cherubic infant, destitute of clothes, shows decided "eventuality;" another in a bewitching bonnet wears a patch over her eyebrow, that marks her perception of time in music. The text that amplifies these desirable qualities abounds in forceful anecdote. George is largely endowed with "benevolence," and chops the wood for his

widowed mother. "Alimentive" Lucy, who stole some grapes, confesses: "Mother, I am the disobedient child, for I did not resist temptation; but they do not taste at all nice now." In short, this handbook is an admirable illustration of the "science" of phrenology, which, as the authoress defines it, is a complete system of mental or moral philosophy.

PARACENTESIS OF THE PERICARDIUM AND ITS ANATOMICAL PRINCIPLES (RUSSIAN). By A. R. VOÏNICH-SÏANOJENTSKIÏ. With 88 Illustrations in the Text. St. Petersburg: S. P. Iakovlev. 1897.

THIS is a most exhaustive monograph on paracentesis pericardii, including a report of a comparatively large number of cases in which the operation was performed to meet various indications. The bibliography is very complete, comprising one hundred and seventy-five references to English and American, Russian, German, and French literature.

AN EPITOME OF THE HISTORY OF MEDICINE. By ROSWELL PARK, A.M., M.D., Professor of Surgery in the Medical Department of the University of Buffalo, etc. Illustrated with Portraits and other Engravings. New York, Philadelphia, and Chicago: The F. A. Davis Company. 1897.

THE history of the science and art of healing should be a subject of absorbing interest to every practitioner of medicine, for it is the history of the age-long strife of truth and error which is to end, we may surely hope, in the gradual triumph over ignorance and superstition. Unfortunately, however, this fascinating study has been beyond the possibility of the average practitioner, since the works on medical history are usually ponderous tomes written by prosy bookworms. Dr. Park has changed this, and has given us a book of moderate size, written in pleasing style, and one which can be depended upon as an accurate sketch of the progress of medicine from the dim past of Æsculapius to the bright present of Lister. Some theologians may take issue with certain portions of the book in which the author complains of the unhappy influence exerted by conservative and bigoted churchmen on medical progress, but no one who believes that there can be no real conflict between true science and true religion will find anything to wound in Dr. Park's statements or comments.

A PRACTICAL TREATISE ON SEXUAL DISORDERS OF THE MALE AND FEMALE. By ROBERT W. TAYLOR, A.M., M.D. New York and Philadelphia: Lea Bros. & Co. 1897.

THE learned author, in this his most recent work, has given us the fruits of his long and varied experience. The anatomy of the sexual organs and the characters of different secretions are given in full detail. Impotence and its functional and organic causes are studied in the most thorough manner. Sterility claims full attention, and after that masturbation, spermatorrhœa, varicocele, and sexual perversion are duly considered. Next comes the subject of sterility in the female, and after that follow several chapters devoted to new growths and other diseases of the female genitals. The entire work is handsomely illustrated, special attention being given to the microscopical appearances of the different lesions.

THE PIONEERS OF HOMŒOPATHY. Compiled by THOMAS LINDSLEY BRADFORD, Author of "Homœopathic Bibliography of the United States," etc., Librarian at Hahnemann Medical College of Philadelphia. Philadelphia: Boericke & Tafel. 1897.

PART I. of this volume of six hundred and seventy-five pages is devoted to the story of the "provers who assisted Hahnemann," Part II. to the pioneer practitioners of homœopathy. An alphabetic table of contents precedes the opening chapters. There is no index.

The biographic part starts off with Adam. After reading the first few lines of this prover of natural products one discovers that not he but a Russian who lived some time later and devoted himself to provings of vegetable charcoal rather than of apples, was the original member of this family. The next candidates for historic recognition, Abner, Anton, and Boehr, have a chapter devoted to them that reads like that well-known one upon the snakes in Ireland. It says: "No data has been obtained regarding these provers." This is almost the shortest chapter in the book, but by no means on that account the best.

Much information of interest has been collected by the author. After Becher is disposed of by quoting Hering to the effect that he "went to parts unknown," we come to Caspari, who, in an attempt to follow the advice of Saint Paul and "prove all things," seems to have got only as far as carbo vegetabilis before he took his departure to realms equally ill defined. As Hahnemann did not seem to have held the gentleman in very high esteem, it is to be presumed that the least said about his destination the better. He left behind him a long list of writings, including a "handbook for the newly married." For any one interested in looking up the men who practised homœopathy prior to 1835 this compilation will be of decided aid, as it is intended to embrace all who in every land had at an early period embraced the faith.

A HANDBOOK OF THERAPEUTICS. By SYDNEY RINGER, M.D., F.R.S., Holme Professor of Clinical Medicine, University College, Physician to University College Hospital; and HARRINGTON SAINSBURY, M.D., F.R.C.P., Physician to the Royal Free Hospital and the City of London Hospital for Diseases of the Chest, Victoria Park. Thirteenth Edition. New York: William Wood and Company. 1897.

THE mere announcement of a new edition of this classic is sufficient for the general run of readers whose guide in the art of healing Dr. Ringer has been for so many years. But a long interval has elapsed since the publication of the twelfth edition, and a new generation has grown up to whom this work may not be so familiar as it ought to be. To them we can only offer our felicitations that they too have the opportunity to turn to Ringer's "Therapeutics" for help in the management of puzzling and refractory cases of disease. The work, as most of us know, is, before all, practical, dealing with the clinical indications and contraindications for the employment of the different remedies rather than primarily with the physiological action of drugs. Much that is new has come up since the twelfth edition was published, and the revisers have added several sections in order to treat of this new matter, which comprises orrhotherapy, the new digestive ferments, the Schott treatment of heart disease, etc. A wise conservatism has, however, marked the work of revision, and no mention is made of many of the new drugs of unknown properties whose only recommendation to professional favor is the assurance of the manufacturing chemist that they will cure anything from hallux valgus to loss of memory. We predict for this latest and therefore best of the many editions of "Ringer" a popular reception equal to if not greater than that given any of its predecessors.

A SYSTEM OF MEDICINE. By Many Writers. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Gaius College. Vol. V. New York: The Macmillan Company. 1897.

THIS fifth volume of Allbutt's "System" treats of diseases of the liver, pancreas, kidneys, lymphatic and ductless glands, and of the nose, pharynx, and larynx, and of obesity. Among the contributors are Drs. Hale, White, Mayo Robson, Dickinson, R. H. Fitz, George R. Murray, Sir Dyce Duckworth, Sir F. Semon, and others whose names are less familiar in this country. The articles are all well written and show fewer marks of the extreme condensation which has marred some of the contributions to the earlier volumes. This is no doubt due to the conviction, which the editor tells us in the preface has forced itself upon him, that it will be impossible to compress the system in five volumes, or in six, including the one on gynæcology, the interjection of which caused such confusion in the numbering of the subsequent volumes of the series. We are glad of this determination of the editor to increase the size of the work rather than to compress injuriously the individual articles. Such well-written and well-constructed articles as are most of this series ought not to be mutilated ruthlessly in order to squeeze them within the pasteboard covers of a single volume. The subscribers to the work would, we are sure, feel amply compensated for the increased expense of the work by the increased value of the separate articles.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 28, 1898.

ARTHUR M. JACOBUS, M.D., PRESIDENT.

Rheumatic Cardiac Diseases and Treatment.—DR. HENRY N. HEINEMAN read a paper with this title. He said that degeneration of the coronary vessels might exist without arterial change elsewhere in the body. In gouty subjects especially all symptoms referable to the heart, whether functional or otherwise, should receive early and careful investigation. In individuals of this class there could be no doubt that the regulation of the diet and proper hygiene were absolutely essential. Meat should be taken in moderation, and, as a rule, liquors should be forbidden. The use of diluted whiskey should be permitted only in times of fatigue, and then only in very minute doses. Some patients, who had long been accustomed to indulgence in wine, did well if allowed a small quantity of claret with meals. The excessive use of liquids at any time should be avoided. The most common cause of cardiac disease was chronic rheumatic endocarditis. Of course, nearly all forms of endocarditis were bacterial in origin. In most cases the mitral or aortic valves assumed a funnel shape, the apex of the funnel pointing toward the heart. At times, the chordæ tendineæ entirely disappeared. What had long been described as "vegetations" on the edges of the valves had been shown by careful miscroscopical examination to be the degenerated remains of the valves themselves. By treating the acute attack of articular rheumatism with large doses of salicylic acid, the valvular complications seemed to have been largely prevented. A fact which had been recognized more than half a century ago, but had been strangely neglected, was that nothing was worse for the welfare of a heart muscle which had once become degenerated than sloth, prolonged sleep, and physical inertia. Twenty-five years ago it was the belief of many that the springs abroad were of value in heart disease chiefly because of the absence of the patient from home and business cares, and also because of the influence of "suggestion." The condition of mind brought out by suggestion exerted the same effect on other diseases than cardiac, and in the same degree, but it was more quickly noticeable in cardiac cases.

Baths.—The famous resort at Bad Nauheim was favorably and pleasantly situated, and had two springs, respectively six hundred and eight hundred metres below the surface. The former threw a jet of water one foot in diameter to a height of fifty feet. Sodium, potassium, and magnesium salts with calcium chloride constituted the principal ingredients, but perhaps the most important ingredient was the free carbonic-acid gas. These were natural thermal waters. They were utilized in the following ways: (1) They were received into reservoirs and were then supplied to the baths at a temperature of from 80° to 94° F.; (2) the waters were received in closed reservoirs; (3) they flowed through iron conduits directly into the bath tub, thus supplying the maximum of heat and carbonic-acid gas; and (4) they flowed into the tub directly, but flowed out again from the openings in the upper part of the tub. When effervescent baths were prepared artificially by chemical means, the gas escaped too rapidly and was of very uncertain quantity. It was well to begin with a bath of four minutes' duration, and gradually increase it to ten minutes. The bath for a woman should be, generally speaking, slightly warmer than for a man, and emaciated persons should receive warmer baths than those who were well nourished. Cold sponge baths were absolutely harmful in cardiac cases, and no patient who had had attacks of angina should be permitted to use them, no matter how long accustomed to them. In the beginning of a course of treatment with these baths, the temperature should be from 32° to 35° C., and it should not be allowed to go lower than two or three degrees below this during the whole course of the treatment. An absolute rule was that a bath the temperature of which was uncomfortable to the patient was one which would fail of its purpose. The baths were best administered in the forenoon, and no exhausting work or walking should precede them. Careful notes should be made, and preserved, of the effects of the baths on the pulse and respirations, and care should be taken to waft away the carbonic-acid gas, which had a tendency to accumulate. The patient avoided inhaling it by turning the head in the opposite direction. The bather should rest for one hour after the bath, partaking meanwhile of some very light and nourishing food.

Exercise.—Massage should be applied in the form of gentle stroking with the flat of the hand. This stimulated the return venous circulation, and equalized its distribution throughout the body. In the later stages it might be applied in the ordinary and more vigorous form. Heart massage, suggested by Oertel, was useful in convalescent cases, and especially when compensation began to fail. It consisted of making compression over the cardiac area during systole of the heart and relaxing it during diastole. For walking, the patient should be clad in warm flannels, and women should wear no stays or corsets. The patient was to be directed to take deep and regular respirations. The walk should be gradually lengthened from a few steps to a walk of five minutes, or possibly even ten or fifteen minutes, provided always it caused no dyspnœa. Hillside climbing might be imitated by going up stairs. No form of exercise out doors subjected the patient to greater danger than hillside climbing, and consequently it should be carried out under direct medical supervision. Treatment by gymnastics consisted in making slight passive movements of the limbs only until the patient was out of bed; then the trunk might be moved, with varying degrees of resistance. No movement should be repeated. The patient's respirations should be deep and regular, and all movements should be performed without jerking. In persons of large physique and flabby muscle these movements might produce enough strain to produce intermittence of the heart action, which was more noticeable in some cases with the movements of the left arm. The Zander movements were characterized by mechanical means under medical supervision.

In conclusion, the speaker said that the baths produced their action (1) by imbibition, some of the salts being absorbed, but more especially by the carbonic acid which reached the nerve-endings and by reflex action influenced the heart; and (2) by the warmth of the baths. In a considerable number of the cases, changes in the size and shape of the heart would be found to take place, the heart becoming firmer and smaller. This had been determined beyond doubt by careful observation. The bath made the pulse fuller and slower. If the pulse became quickened, it should be taken as an indication that the bath had been unduly prolonged. Carbonic-acid gas when inhaled produced a quickening and a hardness of the pulse, which was very different from the effect of these baths.

Recent Improvements in the Treatment of Chronic Heart Disease by Exercises and Carbonated Brine Baths.—DR. T. E. SATTERTHWAITE, in a paper on this subject, stated that he used the resistance movements almost exclusively, the patient making movements

which were resisted by the physician. There was always an intermission after each movement. The hand which resisted grasped the limb with only sufficient force to accomplish the resistance. The patient was instructed to breathe naturally. The movements themselves were flexion, extension, abduction, adduction, and rotation of the neck or limbs or trunk. At first the changes were not very marked. He usually began by simple flexion and extension.

The Special Exercises.—The more important of the exercises were described and demonstrated as follows:

No. 1. The hand of the patient is grasped by the physician with one of his hands, and flexion and extension of the wrists are made.

No. 2. Flexion is made at the elbow, the patient flexing the forearm, the operator resisting, and the arm being returned gently by the patient to the original position.

No. 3. With the forearm flexed, the operator makes resistance while the patient endeavors to straighten the forearm.

No. 4. The patient holds the two wrists parallel, and then they are separated gradually until the arms are stretched out to their fullest extent laterally. The arms are not returned to their original position, because this produces an unpleasant sense of constriction in the chest.

No. 5. The patient, being seated, swings the arm around slowly in a complete circle, the operator resisting.

No. 6. The patient stands with the arms pendent and close to the side. The operator grasps both wrists and makes resistance while the patient raises his arms laterally, and then upward to the full extent above the head. Here again the arms are returned without resistance, to avoid the unpleasant effect on the pectoral muscles.

No. 7. The operator, standing behind the patient, makes resistance while the patient carries the arms outward and upward until they are brought parallel to each other above the head. The return movement is made with slight resistance.

No. 8. The operator stands behind the patient, and makes resistance while the patient, with one foot placed in advance of the other, raises both arms forward.

No. 9. The patient stands against the wall, with one foot seven or eight inches in advance of the body. The operator makes resistance while the patient bends the body forward at an angle of about 45°.

No. 10. The operator twists the patient around a vertical axis, and then the patient untwists himself.

No. 11. The operator makes resistance while the patient endeavors to twist himself around a vertical axis in the direction opposite to that of the preceding exercise.

No. 12. This consists in lateral flexion of the body, assisted by the operator, and then resistance is made by the operator while the patient restores the body to the vertical position. Lateral flexion is then made in the opposite direction.

No. 13. With the patient's leg resting on the operator's knee, the latter makes flexion and extension of the ankle.

No. 14. Flexion and extension are made at the knee with proper resistance.

No. 15. Flexion and extension of the thigh on the trunk are made.

No. 16. This consists in making abduction and adduction of the lower extremities.

A moderate amount of exercise in the open air daily should, whenever possible, be a part of the treatment.

Duration and Temperature.—In the treatment of heart disease by baths, the speaker said, their duration should vary from four to twenty minutes. Their temperature should not exceed 95° F., and should rarely go below 85° or 90° F. At first the baths should be given every other day, but the interval should be progressively increased. The course lasted four or five weeks. The speaker said that there was nothing distinctive about the waters of Nauheim, and the means for artificial baths possessing the same advantages could now be easily obtained in very convenient tablets and powders.

The Treatment Not of Universal Application.—Dr. William H. Thomson said that he would not like the impression to go abroad that heart disease should be subjected in a routine way to baths and exercise, irrespective of the particular lesion and of the individual to be treated. Of course, nothing that had been said by the preceding speakers should be considered as applicable to any case of acute endocarditis. In his opinion, percussion of the heart, as ordinarily performed, gave no information of absolute scientific value. It should never be done with the patient in the prone position, but always when the person was sitting up and leaning forward. Without such precautions percussion was wholly valueless. At the outset treatment must be governed largely by whether the trouble was in the pulmonary or in the systemic circle. If in the pulmonary circle, the treatment of the bronchitis and emphysema would give better results than all sorts of baths and exercises. In a primary endocarditis the valves were everything; in a secondary endocarditis they were almost nothing, the main thing being the condition of the heart wall. He had no question about the benefit to be derived from these baths, provided they were used in properly selected cases. This improvement was due to the peripheral irritation produced. He fully believed that a permanent dilatation of the cutaneous arterioles took place as a result of the baths.

No More Specialists Wanted.—He was afraid that many would gain the impression that these exercises and movements were so complicated that it would be necessary to send patients with cardiac disease to "heart specialists," and he desired, therefore, to protest most earnestly and emphatically against the creation of any more specialists. These movements were not intricate, and could be readily carried out. If after such exercise it was found that the patient's pulse improved and that the respirations became deeper, one could be sure that the treatment was in the right direction.

Dr. W. H. McEnroe took exception to the statement made about salicylic acid preventing the occurrence of rheumatic endocarditis. After the urine had been made decidedly alkaline by the old alkaline treatment, then the salicylates could be used with benefit.

Useful in Other Diseased Conditions.—Dr. J. C. Minor said that if it were once understood that this method offered all the advantages of digitalis and strychnine without any of their limitations; that it had all the advantages of bleeding, without the loss of blood; and that it possessed, to a marked degree, the power to stimulate functional activity generally—it would be readily accepted as a method having a firm and rational basis. We must assign to the saline ingredients of the baths a reflex action through the terminal nerves of the skin—the theory advanced by Dr. Theodore Schott. That the nerve centres were powerfully influenced seemed to be proved by the marked trophic changes observed after such a course of treatment. The improvement progressed sometimes for months after discontinuance of the treatment. The carbonic acid of the baths acted directly upon the vascular system, and so afforded relief to an overdistended and laboring heart. The treatment would also be found useful in other conditions. It had seemed to

him a rational one for exophthalmic goitre, and a case of this kind now under the treatment had responded in an encouraging manner. In using these baths he ordinarily began with an effervescent bath, adding five pounds of chloride of sodium to fifty gallons of water.

Baths Act More Quickly than Exercises.—Dr. Reeves said it had been claimed that the Nauheim treatment was applicable in all cases of chronic heart disease, except those in which there was advanced arterial sclerosis, kidney disease, or acute pulmonary congestion. From observations at Nauheim he was convinced that such was the case. Marked chronic congestion of internal organs should be first relieved as far as possible. When these were not excessive, good results were obtained at Nauheim. The treatment was applied there, with success, in both aortic regurgitation and mitral disease. He had also seen very striking results in cases of cardiac degeneration —fatty or sclerotic heart. Our climate was not well adapted to this treatment; hence he was disposed to omit the baths from December to March. He shared the opinion of many others, that the baths produced quicker results than the exercises, and that the best results were seen from the exercises when the patients were well on the road to convalescence. It was very important to use a bathtub very much larger than those generally in use in dwelling houses. At Nauheim the tubs were large enough to allow of the immersion of the patient up to the neck.

No Peculiar Virtues in these Baths and Exercises.—Dr. Beverley Robinson said that he was sceptical about there being anything especially beneficial in these particular baths; equally remarkable results would be claimed by the physicians at the sulphur baths in the south of France. He was disposed to make a similar criticism about the exercises. In his opinion, it was time to protest most emphatically against attaching too much importance to any learned disquisitions on the very small features of a very large part of the daily practice in medicine.

Digitalis Made Available in Advanced Cases.—Dr. Heineman, in closing the discussion, said that a long series of experiments had been made years ago with saline and other baths of varying strengths, and it had been demonstrated beyond question that the results were different with different strengths of saline solution. The paper that he had just presented was based on much careful observation at Nauheim, extending over ten summers. It was only too well known that a time would come when digitalis would fail to do good. It would be found that after a course of these baths the digitalis would display all its old-time virtue. It was true that observers differed regarding the best method of percussing the heart, but for purposes of comparison it was necessary only to see that the same method was adopted in each instance. A number of *x*-ray photographs were then exhibited as conclusive proof of the statement that had been made regarding the diminution in the size of the heart observed in many cases receiving treatment at Nauheim.

Dr. Satterthwaite said that the series of gymnastic exercises described by him was simplicity itself, and it was for this reason that they had been particularized. Such exercises could be increased or diminished as required in the individual case, and they had the advantage of being safe. He wished to disavow most emphatically any desire to pose as a "heart specialist." His object in presenting the paper was, on the contrary, to show how much could be accomplished in chronic heart disease by any medical practitioner. It was the treatment *par excellence* for heart failure, especially after the ordinary medical treatment had failed.

Report of Special Committee on the Health Board.—Dr. H. G. Piffard, on behalf of this committee, reported that it had submitted to the legislature a brief, in which the main reasons for the passage of the health-board bill had been stated. As there had apparently been a good deal of misunderstanding regarding the purpose and provisions of this bill, the greater portion of this brief was read. He said that before its introduction into the legislature, the Brush bill had been indorsed by the two new commissioners of health. The chief objections made to it were: (1) that if it should pass, the health department would be unable to continue its laboratory work, as this was supported by the profits derived from the sale of the products of the laboratory; and (2) that its power to cope with tuberculosis would be seriously curtailed. The committee, however, was of the opinion that the private sale of the products of the laboratory was unwise and liable to serious abuse, and that the necessary means for laboratory work could be provided, as the public was in hearty sympathy with it. The omission of pulmonary tuberculosis from the list of contagious diseases to be reported hinged upon the question as to the advisability of including tuberculosis in a permanent enactment, as distinguished from a temporary enactment. The committee had now decided that it was wiser to withdraw all amendments to this section, leaving the charter as it stood before. The ultimate solution would be left to the wisdom and discretion of the municipal assembly of Greater New York.

Formal Indorsement of the Bill.—Dr. E. H. Grandin then moved that this bill receive the formal indorsement of the society. The motion was carried unanimously.

Dispensary Bill.—Dr. J. H. Burtenshaw stated that the dispensary bill was still in the committee on public health of the senate and assembly. In order to hasten its passage, the following resolutions were offered by him and adopted by the society:

"*Resolved*, That the Medical Society of the County of New York reaffirms its indorsement of the bill to amend the State charities law, regulating the licensing and regulation of dispensaries by the State board of charities, now before the legislature of the State, and that it urges the immediate passage of the bill in its present form; and

"*Resolved*, That this resolution be signed by the president and secretary of this society, and that copies be forwarded to the lieutenant-governor, the speaker of the assembly, and the chairman of the senate and assembly committees on public health."

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, February 15, 1898.

Dr. Louis Faugères Bishop, Chairman.

The Feminine Element in General Practice.—Dr. Eugene Coleman Savidge read a paper with this title (see page 405).

Dr. W. H. Draper said that there seemed a bit of opprobrium in the term "feminine element," and that he rather preferred to think of women in another relation than that suggested by the paper. He had had recalled by the paper some other transfers from medicine to surgery. He could remember the time when pleurisy with effusion, empyema, and pericarditis were treated by the physician. They were now surgical diseases. He thought the time would come when physicians would perform these operations themselves. He thought that most practitioners were conscious of a "feminine element," and modified their attitude accordingly; nevertheless he was not inclined to think he would treat scarlet fever or typhoid fever in a wo-

man any differently than in the case of a man; but he agreed with the writer of the paper that the genital organs of women when diseased would modify the general organism, and that the general practitioner was the sanitarian, and should have sufficient knowledge of these diseases to warn against their approach.

Dr. W. H. Thomson said that the subject had been ably presented, but it was large enough to reach around the earth. Limiting himself to a few points in regard to the feminine element, he would emphasize the fact that there were certain diseases that fell upon women a great deal more frequently than upon men; for example, membranous colitis, which was found six times as often in women as in men; and, again, hysteria, of which there were eighteen female cases to two male cases. There was also Graves' disease, which was essentially a female trouble, for he did not believe at all that it was because of any difference between the thyroid gland of the male and the female. He thought that if one could get at the reason why these troubles attacked the female more frequently than the male, he would get a clew to the feminine element. Dr. Thomson cited a case in which there had been sudden suppression of menstruation and urine, intestinal paralysis followed by stercoraceous vomiting, and a copious increase in activity of the salivary and lacrymal glands, the secretions of which when tested yielded crystals of nitrate of urea; in other words, the chronicity of the visceral functions had been arrested by pelvic irritation—by a cold during menstruation—and the poor girl had been literally turned upside down.

There was another point mentioned by Dr. Savidge which he wished to second heartily, and that was the modification entailed upon women by civilization, and the bearing of muscular power upon general and local conditions. Every cell in the body respired as well as the lungs; oxygen was necessary for all; but one tissue required more oxygen than any of the rest, not even excepting the nervous system, and that was the muscular tissue. And by muscular tissue he did not mean the skeleton muscles, but the rhythmic muscles lining the tubular canals of the body. Indoor life had so enfeebled the muscular powers of woman that she fell readily under the woes mentioned by Dr. Savidge. Among nomadic races, for example, he had himself seen an Arab woman carrying a bundle of sticks upon her head give birth to her child, deliver herself of her placenta, place the child with the sticks upon her head, and resume her journey. He believed that if we could collect a number of these women and let Dr. Savidge circulate among them, that gentleman would find very few of the long list of troubles he had enumerated in his paper; and the reason for the immunity was the outdoor life and consequent muscular power.

Dr. E. B. Cragin said that he supposed he was expected to say a word on the gynæcological side of the question. Inclination or opportunity had impelled men to take up separate lines of work. Some were surgeons and found themselves limited to surgery, and sometimes with regret realized that they were losing their former medical skill, when they were listening daily to chests. Others were medical men, with the limitations of medical men. He deprecated a too narrow specialism which would see everything through a speculum. There were a great many troubles which might be cured medically, which were nevertheless attacked surgically for the reason that it was shorter and more permanent in result; for example, curetting for an endometritis instead of the more uncertain treatment by ergot and hydrastis. He thought that Dr. Savidge bore quite evenly upon the gynæcologist and general practitioner. He had shown that the gynæcologist was as apt to overlook the medical side as was the medical man to neglect the local condition. He wanted to emphasize one point raised by the paper, and that was the importance of attention during the puerperium. By this he did not mean simply asepsis or care at the time of delivery, but during the subsequent period, when malpositions, subinvolution, lacerations, etc., could be easily corrected and many women saved from the gynæcologist. He thought that Dr. Savidge had presented a paper of great value.

Dr. Mary Putnam Jacobi expressed her interest in the paper, and likewise deprecated a too narrow specialism. She thought it a misfortune that because a practitioner was known to be skilled in a certain line the conclusion must therefore be drawn that all patients coming to him were necessarily afflicted with troubles in that branch of medicine. She wished to call attention to two details in the paper. One was that atmospheric pressure would affect the veins between the broad ligaments. Lowered atmospheric pressure would allow an increase in blood pressure in the superficial veins, but would deplete instead of engorging the viscera. The other detail was Dr. Savidge's statement that retrodeviation would cause a congestion of the uterus "like a string around the finger." She had heard Dr. T. Gaillard Thomas say the same thing twenty years before; but in the light of later literature it was now known that this uterine congestion was not caused by constriction, but by the difference in the curvature between the arteries and veins. Dr. Jacobi agreed with the author that fatigue and general debility and congestion very often affected the local organs. In some of these cases, however, she deprecated local treatment, as for example an engorged uterus, which was merely an expression of a congestion of the liver.

Dr. Charles L. Dana said that, speaking from his own individual experience, he was inclined to doubt the efficacy of local treatments in nervous disorders. He had always been conscientious in having local examination made when he suspected serious local disorder; but in some cases he thought it would do positive harm to have even so much as an examination made. He had seen at his office many cases that had been through gynæcological treatment, and had come to the neurologist as the last resort. In some cases the local examination would call a young woman's mind to her local condition and set her to speculating as to the location and condition of her ovaries and womb, and give her a trend of thought apt to remain a long time. He had even seen harm done to the nervous system by the minor procedures such as curetting. Perhaps he should not make a broad generalization from his own experience, but at least he had never seen a case in which true epilepsy had been caused by any pelvic condition or cured by any pelvic attention.

Dr. Savidge, in closing, said that he thought he had made out the contention of the paper, namely, that there was a common ground on the border line between the specialties which could be turned over with great profit.

Extra-Uterine Pregnancy.—Dr. J. P. Nedoroff (section for obstetrics and gynæcology. Moscow, August 24, 1897) says of extra-uterine pregnancy: 1. That ectopic gestations of one month's duration should be treated with the electric current, and that the middle of the fourth month should be looked upon as the border line of the period during which the electrical treatment is applicable. 2. That in hæmatoceles following extra-uterine pregnancy it is the only possible treatment up to the third month, and even older cases of hæmatocele should be dealt with in no other way. 3. The remaining cases are to be treated surgically.

Therapeutic Hints.

For Corns. —

℞ Potassii caust. 5
Aq. dest. 40
Glycerini 20
Tr. iodi 5
S. Apply morning and night with caution.

Burns.—Immerse the burned part in a bath containing a few teaspoonfuls of potassium nitrate, or apply a bandage wet with the solution. Phlyctenæ are said to be prevented.—Poggi.

Red Nose.—Scarification, acupuncture (forty sharp points mounted on a solid disc), by means of electromotor. In rhinophyma, ablation and Thiersch graft. —Lassar.

Intertrigo.—No treatment has been found superior to painting each day with:

℞ Methylene blue ..... gr. v.
Spt. vini rect. ..... ℥ss.
Liq. potassæ ..... ♏v.
Aquæ dest. ..... ℥ij.

A disadvantage is the staining of clothing.—C. W. Allen.

Seborrhœa Capitis.—

℞ Saponin ..... gr. xx.
Tr. benzoin ..... i.
Aquæ dest. ..... ss.
Glyc. ac. carbol. ..... i.
Spiritus odorati ..... ad iv.
M. S. Apply as shampoo.

—Skinner.

Furuncle of the Eyelid.—

℞ Tr. camphoræ ..... ♏xv.
Sulphuris precip. ..... gr. xv.
Aq. calcis,
Aq. rosæ ..... āā ℥iiss.
Gum. acaciæ ..... gr. iij.
M. S. Apply.

—Landolt *and* Gigax.

Bronchiectasis in Children.—

℞ Eucalyptol 10
Creasoti 25
Tr. benzoini 50
Copaibæ 50
Ol. amygd. amaræ ..... q.s. ad 200
M. S. Thirty drops daily, per rectum, in a little milk. Gradually increase dose to one or two teaspoonfuls.

—Molle.

Dysmenorrhœa.

℞ Ext. belladonnæ,
Ext. stramonii ..... āā 0.1
Ext. hyoscyami 0.2
Ammonii sulphatis 1.5
M. et ft. pil. No. x. S. One every four hours until relieved.

—Justin Steer.

Spasmodic Asthma.—

℞ Tr. stramonii ..... ℥ij.
Ammon. carb. ..... i.
Sodii bicarb. ..... ℥iij.
Magnesii carb. ..... i.
Pulv. rhei ..... gr. xx.
Chloroformi (purif.) ..... ♏xx.
Aq. menth. pip. ..... q.s. ad ℥viij.
M. S. One-half ounce to be taken t.i.d. with one ounce of water.

—Murray.

Chocolate Emulsion of Cod-Liver Oil.—

℞ Chondri mucil. N. F. ..... ℥v.
Ol. morrhuæ ..... ℥viij.
Glycerini ..... ii.
Theobromæ pulv. ..... i.
Tr. vanill. ..... ℥iij.

Rub the cacao with the mucilage, and heat until a uniform mixture is obtained. When cold, add the cod-liver oil and glycerin, and beat up with an egg beater.—W. A. McIntyre.

Sudorific for Children.—

℞ Infusi boraginis et sambuci 150
Vini portensis 50
Tincturæ aconiti 0.65–1.23
Sodii salicylatis 0.50–2
Syrupi diacodii 30
M. S. One tablespoonful every hour.

—Teixeira.

Acute Pneumonia, to Encourage Expectoration.—

℞ Tr. opii deodorat. ..... ♏v.
Ammon. muriat.,
Ammon. carb. ..... āā gr. vij.
Tr. cubeb. ..... ♏xv.
Syr. tolutani ..... q.s. ad ℥ij.
M. S. Every three hours.

—Adolph Zeh.

Gonorrhœa.—

℞ Methyl salicylate ..... gr. xv.
Bismuth subnitrate ..... ℈v.
Liquid vaseline ..... ℥ij.
M. S. Use thrice daily after passing water; retain injection as long as possible.

—Duquaire.

Whooping-Cough.—

℞ Potassii cyanid. ..... gr. iss.
Morphinæ acetatis ..... gr. ¼
Acid. acetici dilut. ..... gr. xxx
Syr. tolutani ..... ad ℥ij.
M. S. For a child of five years.

—Cleland.

Unilateral Parotitis with Carious Teeth.—

℞ Ung. belladonnæ,
Ung. hydrarg. ..... āā ℥ss.
M. S. Apply night and morning.

Also:

℞ Cinchonidinæ salicylat. ..... ℈i.
Div. in tabulæ No. xx. S. One every three hours.

—Eshner.

Mammary Abscess.—

℞ Glycerin ..... ℥ss.
Sterilized water ..... ℥vi.
Alcohol ..... ℥iss.
Biniodide of mercury ..... gr. ij.–iv.
Potassic iodide ..... gr. v.
M. S. Soak tarlatan in this and apply to the inflamed area.

—Tarnier.

Calomel Treatment of Hemorrhoids.—Detrue (*Arch. Méd. Belges*, No. 7, 1897) recommends Brindley's method, and employs powdered calomel or the following ointment:

℞ Calomel. ..... 2 gm.
Morph. hydrochlor. ..... 0.025 gm.
Bismuthi subnit.,
Vaselini. ..... āā 25 gm.
Glycerini ..... 8 gm.
M. ft. ungt.

To Cure Itch in Two Hours.—Vleminkx recommends fresh sulphuret of calcium made as follows:

℞ Sulphur (flowers) ..... ℥iij.
Quicklime ..... ℥vi.
Water ..... Oij.

Boil together till combined, then allow to cool and settle. Decant and preserve in hermetically sealed bottles. Application: Rub patient all over with soft soap for half an hour, then place in a tepid water bath for another half-hour. Next rub over with the solution and allow it to dry on the skin for a quarter of an hour. Complete by washing in the bath.—*Canada Lancet.*

Summer Diarrhœa.—In the treatment of the summer diarrhœas of children, S. Solis Cohen recommends, in addition to strict diet and mild laxatives, a combi-

nation of salicylate of bismuth and benzonaphthol. He gives a six-months child one decigram of each every two or four hours at the beginning; later less frequently.—*Medical News*, 1896, p. 203.

In Asthma Associated with Emphysema.—

℞ Potassii iodidi..... gr. v.
Liquor. potass. arsenitis..... ♏ iiss.
Elixir. simplicis.....q.s. ad ʒ i.
S. One drachm after meals and at bedtime. Increase the dose if necessary.

—J. C. Wilson, *Dunglison's College and Clinical Record*, January, 1898.

For Pigmentary Blemishes of the Skin.—

℞ Corrosive sublimate..... 0.5 gm.
White sugar..... 15 "
White of one egg.
Lemon juice..... 30 "
Distilled water..... 250 "
M. S. To be applied every morning and allowed to dry on the skin.

—*Journal de Médecine de Paris.*

For Bronchial Asthma.—

℞ Sodii iodidi..... 4
Ammon. carb..... 4
Tinct. lobeliæ..... 8
Spir. chlor..... 15
Vini ipecac..... 4
Infus. senegæ.....q.s. ad 180
M. S. Tablespoonful in water every three or four hours.

—Rainear, *in Codex Medicus.*

Treatment of Severe Syphilis.—In three cases of severe pulmonary, bone, and cerebral syphilis, when "mixed treatment" failed, metallic iodine gave good results.

℞ Iodini pur..... 10 gm.
Potass. iodid.....ad sol. q.s.
Glycerin..... 10 gm.
Acid. citric..... 15 gm.
Syr. simp.....ad 1,000 gm.
M. S. Two tablespoonfuls daily, increased by one, until daily dose equals nine.

—Bouveyron, *Klinisch-therapeutische Wochenschrift.*

Acetate of Aluminium in Uterine Hemorrhage.—Solution of aluminium acetate is recommended by Dr. Kalenscher (*Munch. med. Woch.*, No. 1) in all cases of post-partum hemorrhage, whether due to inertia, abnormal location of placenta, placenta succenturiata, etc. Injections of from twenty to thirty centimetres of the solution are made, through a curved hard-rubber uterine catheter.

Guaiacol in Gonorrhœal Epididymitis.—The scrotum is pencilled with pure guaiacol, or with a fifty-per-cent. solution in glycerin; or a salve, not weaker than twenty-five per cent., may be applied.

℞ Guaiacol..... 10
Lanolin,
Resorcin.....āā 15

After application the fever and pain disappear, and in a few days a complete cure results. The guaiacol is discontinued as soon as swelling ceases, since the drug has no resorptive power. On account of its liability to produce toxic symptoms, not more than 0.5 gm. should be used daily.—Goldberg, *Deutsche medicinische Wochenschrift*, No. 32, 1897.

Treatment of Neuralgia of the Spermatic Cord.—Domino (*Berliner klinische Wochenschrift*, September 27, 1897) recommends methylene blue. In a case that resisted all previous treatment, and when castration was being seriously considered, methylene blue was administered in doses of 0.1 gm. every two hours. After the third capsule the pain became less severe, and disappeared altogether after the fifth dose. In all, twelve capsules were taken. The patient has had no recurrence. A similar result was obtained in a case of neuralgia of the testicle.

For Pernio.—

℞ Plumbi acetat.,
Alum pulv.....āā 5
Cetac.,
Cer. alb..... 30
Ol. oliv..... q.s.
M. et ft. ung. molle. S. Apply evenings.

—*Centralblatt für die gesammte Therapie.*

Drugs which Should Not be Dispensed in Capsule Form.—Salicylate of sodium causes gastric disorders, with nausea and vomiting, and should therefore be administered diluted with plenty of water. Ulceration of the gastric mucosa has been observed after its use in capsule form. Antipyrin often irritates the digestive tract, and is best given in vichy or soda water. The following drugs are hygroscopic and therefore cause the capsule to become softened: acid phosphates and glycero-phosphates, sodium bromide, crystallized calcium chlorate, strontium chloride, piperazin, lysidin, chloral, the dry extracts of plants, and in general those preparations produced by evaporation in vacuum. Some solid drugs when mixed tend to deliquesce—mixtures of antipyrin and sodium salicylate, for example. Certain substances, when exposed to the air, become altered or at least discolored by the contained oxygen. The chief representatives of this group are the salts of iodine, the alkalies, and the alkaline earths; also aristol. Free iodine combines with the starch of the capsule, producing a bluish-black discoloration.

Palatable Castor Oil.—

℞ Pulv. acaciæ..... ʒ iv.
Ol. ricini..... ʒ i.
Elix. simp..... ♏ xx.
Ol. amygd. am..... ♏ i.
Ol. caryophylli..... ♏ ij.
Aq. dest.....q.s. ad ʒ ij.

Dissolve the gum in sufficient water and add the oil gradually; lastly add the flavoring.—*London Practitioner.*

Injections of the Benzoate of Mercury in Syphilis.—The benzoate of mercury should not be prescribed in saline solution, since double decomposition occurs with the formation of bichloride of mercury. Instead of sodium chloride ammonium benzoate should be employed as in the following formula:

℞ Hydrarg. benz..... 0.3 gm.
Ammon. benz..... 1.5 "
Aq. dest. ster..... 30 "
Of this inject from one to two cc. daily for one month.

—Gaucher.

For Fistula in Ano.—Olive oil, boiled and cooled, to which has been added one grain of carbolic acid to the drachm, makes a most grateful application after operation for fistula in ano. Apply by saturating aseptic gauze and packing the fistulous tract.—Hearn.

Picric Acid in Chronic Gonorrhœa.—Bochon (*Méd. Mod.*, No. 1) recommends picric acid in chronic gonorrhœa and claims cures after from four to ten injections. In cases in which the pus is free from gonococci and contains but a few formed elements, he employs a solution in the strength of 1 to 100; when the pus is rich in formed elements he begins with a 1 to 200 injection; as soon as gonococci are present, an injection of silver nitrate, 1 to 50 or 1 to 30, is made, and on the next day picric acid, 1 to 200, is used, and on the following day 1 to 100. The instillations are made every second day, are painless, and cause very slight reaction.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CONCLUSION OF THE DEBATE ON MAMMARY CANCER —DR. MAGUIRE ON PALPATION OF THE CHEST AND ABDOMEN — SMALL-POX AT MIDDLESBOROUGH — DEATHS OF SIR J. MACKIE, SURGEON-GENERAL MACLEAN, AND DR. DRUCE J. SLATER.

London, February 25, 1898.

The adjourned discussion on mammary cancer was resumed on Tuesday by Mr. Pearce Gould, who remarked on the difficulty of discussing a disease of so protean a character, which may kill in a few months or last for thirty years, remain local or become generalized, and whose secondary growths increase slowly or very rapidly. From the statistics of the Middlesex Hospital for the last ten years it seemed doubtful whether long immunity was due to operation; whether a return after long immunity was a recurrence or a fresh outbreak. He considered it to be the former, except when the growth appeared in the opposite breast; for late recurrences occurred in the same situations as early ones and in positions where primary carcinoma could not occur. As to the effect of operation, if it simply removed an infected and infecting centre, it was only like an amputation, which was not a "cure." The wider the operation the longer the immunity, the less likelihood of local but the greater of visceral recurrence.

Mr. Watson Cheyne advocated removal of the primary lymphatic area in every case, as recurrence was very irregular. He agreed with Heidenhain and Stiles. The question was whether to be content with from ten to eighteen per cent. of recoveries or to resort to more extensive operations that gave from forty to fifty per cent. The frequent recurrence in the axillary glands was a strong argument for their removal. As to the term "cure," statistics of the old operation showed that eighty-five per cent. of those who remained immune for three years had no recurrence. With the wider operation he anticipated that the percentage would be under fifteen. If there was no recurrence three years after removal of a large tumor, he would not expect any. But the prognosis of atrophic scirrhus was not so good. As to more frequent internal deposits after the Heidenhain-Stiles operation, he said ninety per cent. of all fatal cases had visceral growths. Under the old operation local recurrence might kill before the internal reached any size; but under the new, if any recurrence took place, it would be internally.

Dr. Norman Moore regretted that the pathological aspect of the question had been neglected in the discussion. He doubted if we had evidence that second attacks occurred. Two independent attacks in the same patient were extremely rare. An attempt should be made at the time of operation to discover if internal deposit had taken place. Much was known of the localization of secondary growths, but there were certain special groupings, such as that of the kidney and heart, secondary to cancer of the œsophagus.

Mr. W. H. Bennett protested against recurrences being regarded as repeated attacks, such as occur of pneumonia. This tends toward resolution, but cancer is naturally progressive. He removed the breast freely and cleared out the axilla, but left the pectoral muscle unless it was involved. He had seen recurrence in muscle, but it was very rare. He wished to know whether the benefit of the new procedure corresponded with its greater severity and whether the mortality was increased.

Mr. Treves said we knew little more of cancer now than at the beginning of the century. He thought the cases related did not show the new operation in a brilliant light, and the old did not deserve the contemptuous remarks made on it. He mentioned two cases with deplorable results—recurrence in a year—in both scar and axilla, arm fixed to trunk, hand œdematous, constant pain, and in one case paralysis.

Mr. Sheild then replied. Of course he could not go through the whole of this lengthy discussion again, and he had not anticipated that it would develop in the directions it had done. He agreed that terms should be used accurately and that "cure" should not be used of malignant disease in the same way as of a lipoma.

I may add that this is by no means the only word used indefinitely in the course of this debate. Old and new, complete and incomplete, small and large, and other phrases were used without much care; while immune, latent, and other words were used in diverse senses by different speakers.

Dr. Robert Maguire demonstrated at the last meeting of the Medical Society a method of palpation and auscultatory percussion which some of the journals, as well as a number of the audience, seem to regard as a novelty. It has, however, been used by a few for a long time with more or less success. The late Mr. Kingdon relied upon palpation to an extent which surprised some of his confrères and caused others to doubt the possibility of their attaining the same degree of accuracy. He held many years ago, among other appointments, the surgeoncy to a life assurance office, and although it was no part of his duty to auscultate the chest, having a medical colleague to do that, he would examine by palpation and reach conclusions which generally tallied with the physician's auscultatory results. This was particularly remarked after his deafness threw him altogether on this method of diagnosis, as I was informed by his colleague. Dr. Maguire has convinced himself of the value of palpation in both thoracic and abdominal examinations, and finds that the sternum does not hinder him from defining the outline of the heart by passing the fingers over the parietes. In the same way he can show the outline of the kidneys or the upper border of a pleural effusion, while small areas of former pneumonia or pleurisy may be discovered in this way when percussion fails. Of course every one who practises percussion knows that the sense of resistance is an important factor, and Dr. Maguire says that with increasing experience the operator comes to rely more and more on this and less and less on the sound elicited. He has reduced the method to a system, in which he presses lightly and alternately with the first and second fingers of his right hand on the body wall, using only a little more pressure than one employs in examining the eyeball for glaucoma. After a little practice, he says, it is unnecessary to use the two fingers alternately, and it suffices to pass the fingers over the chest-wall, pressing lightly. In this way the fourth interspace will be found harder than the first, from the presence of the heart beneath. So the seventh will give the liver resistance if compared, for example, with the second. He even asserts that on testing through the sternum opposite the first and fourth spaces, the resistance of the heart may be felt at the lower level. Again, over the abdomen he finds palpation more delicate than percussion.

After this it is a matter of course to hear that Dr. Maguire finds auscultatory percussion a valuable method of examination, though by no means capable of determining the size of the heart, as proposed at Nauheim.

Small-pox increases at Middlesborough. Up to yesterday four hundred and ninety-five cases were notified.

Sir James Mackie, M.B. Aberdeen, K.C.M.G., died on the 23d inst., at Alexandria, in his sixtieth year. He graduated in 1860 and went to Egypt the following year. He was for a long time on the Egyptian quarantine board and represented the British government at the international conference at Venice, 1891. He was the recipient of many honors and greatly esteemed.

Surgeon-General Alexander Maclean, M.D., died suddenly last week, aged sixty-six years. He entered the army in 1854 and served in the Crimean war and the Indian mutiny.

D. J. Slater, M.D., London, met his death by the discharge of both barrels of his gun as he was returning from a day's shooting. Both charges lodged in his chest, and he was able only to say "I fell," when found by the keeper. He was a keen sportsman. He took his M.B. in 1883, M.D. in 1888.

THE DIFFERENT FIELDS OF OPERATIVE SURGERY AND GYNÆCOLOGY IN EUROPE.

To the Editor of the Medical Record.

Sir: Dresden is southeast from Leipsic seventy-four miles. It is the capital of Saxony, and has been the home of sovereigns for nearly five hundred years. Though a city of only 335,000 inhabitants, it is a place of great splendor in art and culture. It has no university, but there are hospitals with abundant material and operators of a high grade, who give interesting clinics for graduates in medicine only. The Carola Haus has more than two hundred and fifty beds, mostly surgical, and under the direction of Hofrath Credé. His father was professor in the university at Leipsic, and first taught the expression of the placenta by external manipulation *à la mode* Credé nearly a half-century ago. The son may make a more lasting reputation from his investigations and experimentations with the silver salts. In his laboratory he showed me the effect of these salts on streptococci, staphylococci, and the various contagious and infectious cocci. The silver not only kills the bacteria but it prevents their growth. It also produces in culture media a sterile zone extending one and one-half or two inches from where it rests in the centre of the glass, while in a similar vessel with the same culture media he had negative results with iodoform, copper, and gold. He has been using chiefly the oxide and citrate salts of silver; the nitrate seldom. He showed me unminted pure silver, which is very brittle, and illustrated its solubility by dropping small pieces in simple drinking-water, which it readily turns dark. He drank it like claret, and at his urgent request I joined him. While not particularly palatable, is not unpleasant to the taste. It does not stain the teeth or the tissues; it colors dark the skin when strong, but the discoloration is easily rubbed off. Of this unminted silver he makes an ointment, combining it with vaselin in the strength of one to ten and flavoring it with compound benzoin ointment. He uses it for destroying sepsis by simply rubbing it into the skin—on the arm at one time and on the thigh at the next. In acute infectious and contagious diseases, such as diphtheria, scarlatina, erysipelas, phlegmon, etc., it is applied twice in twenty-four hours usually, but in no case oftener than three times, the third application being made after the lapse of twelve hours. He asserts that he has not found a case in which it was necessary to apply this ointment more than three times for the effective destruction of acute sepsis in the foregoing diseases. In cases of syphilis he has abandoned mercury and uses this ointment instead; but in these cases he applies it for an indefinite length of time. When first applied to the skin it colors it black or dark, but when rubbing is continued for fifteen to twenty-five minutes the dark color disappears. When I inquire whether there is danger of argyria from prolonged use of these drugs internally and endermically, he replies emphatically, No, except from the nitrate salt, which, he claims, is unlike his preparations in almost every respect. The other two salts which he chiefly uses are sold under the names of "itrol" and "actol." He explains that it is necessary to prefix one letter to each and we have the correct names, *c* before itrol making citrol, and *l* before actol giving lactol. The citrate, in a solution of 1 to 8,000, will kill gonococci, but it may be used as strong as 1 to 4,000, the latter being the saturated solution of this salt, and this is therefore the one to be placed in the hands of a patient. It is harmless in saturated solution. The lactol solution may be made as strong as 1 to 15, which is too strong for ordinary use and should never be placed in the hands of a patient except in such cases as a physician may indicate. In this strength the solution is for the physician only. In dressing wounds Credé doubts the efficiency of the saturated solution of the citrate and always uses the lactate; when a wound is aseptic, 1 to 5,000; when septic, 1 to 1,000. In the latter strength he prepares catgut sutures within a large-mouthed bottle, blackened to prevent action of light on the silver solution. Catgut remains in this solution one week; silk, two weeks. Before being sterilized in this solution catgut is cut into lengths of thirty centimetres, and when removed these lengths are wrapped in gauze, laid straight, and so placed in tin cans for a week, when they are put in alcohol, in which they remain until used, perhaps months later. Credé has one large flask of sublimate solution in his operating-room, simply because silver solutions are not permanent in light and there are times when he must have an antiseptic solution before he has opportunity to prepare one; the sublimate is always ready, though he seldom uses it. Except this sublimate solution, there is absolutely no antiseptic besides silver. The latter he prefers to sublimate, and uses it in nearly every case alone. He showed me a case of pyothorax operated on five days before and washed out only with silver solution. The patient was a lad of about fourteen years. The edges of the wound were not red, nor were they angry in any way. There were no eruptions around the border, no pain, no swelling. The cut surface was soft and flabby, not even tender to the touch. The little fellow helped to hold the tubing while the cavity was being douched, coughed when told to do so, and turned himself in the bed; he sat up or lay down as requested, without complaint or evidence of suffering. In the wards various wounds were shown me from operations for many kinds of sepsis, and the non-inflammatory soft condition of the tissue in and around the incisions was marvellous. Credé does not use iodoform gauze nor does he sterilize his gauze for dressing wounds; he does not sterilize cotton wool or bandages—not because he does not believe in antisepsis, but that it may not be said his results are due to asepsis or to antiseptics other than silver. He is convinced, and wants to convince others, that he has developed altogether the most potent antiseptic ever known to man and one of a most practical character, it being simple in application and economical in the small amount required for each dressing; the saving to the Carola Haus annually is quite material, since he uses only silver. After operation, when there is sepsis or when Credé is in doubt, he dusts into the wound a very minute quantity of the silver lactate. Over this he binds cotton or gauze that is neither medicated nor sterilized. He also has a gauze which is impregnated with a silver solution and is quite dark. This he tells me is quite expensive, but he uses it on rare occasions, when a

wound is deep, narrow, and oozes septic secretion freely.

The Corola Haus is not supported by the government or the city, the funds coming from endowment by wealthy individuals—patients and friends. Credé has had control of the surgical department for six years, and for two and one-half years has used only silver for antiseptic purposes, with much better results than were formerly obtained. He treats about one thousand surgical cases here annually. Some distance from the Corola Haus Credé has a private hospital for gynæcological patients, in which line he is a well-known operator.

Leopold has a gynæcological and obstetrical hospital and clinic at No. 25 Seminary Strasse, on the second floor. He has no amphitheatre and there is no good light in his operating-room, but I find some six or seven doctors attending his clinic. Leopold is a learned man in pathology and makes apt use of this knowledge in teaching diagnosis. He has rooms furnished and resides within the hospital, receiving besides 5,000 marks per annum. None of his assistants or visitors are permitted to attend any other clinic while attending Leopold's. All his assistants are not only German, but are strictly Leopold German. Leopold is not cosmopolitan in his ideas or in his operations, but he is a quick, nervous man, who wields a knife with admirable confidence.

From Dresden, almost due south one hundred and twenty miles, we are out of Germany and in the interesting Bohemian capital, where only a few weeks previously the storm in the parliament at Vienna had formed a new cloud which broke like a thunderbolt in the form of a mob before which the police force was as chaff before the wind, and which was quelled only by the soldiers, but not until after considerable bloodshed. The Emperor issued an edict that each and every man who made an inflammatory speech touching the political issue which had created this mob should be peremptorily hanged. I was in Prague at the expiration of this edict, which had been in force for thirty days, but I could detect no difference in the perfect peace which I had noticed on previous days. The route from Dresden is through the celebrated Saxon Switzerland, along the river Elbe, and affords the finest views of the scenery of that beautiful stream and its picturesque mountains. Prague has 183,000 inhabitants, is the capital of the kingdom and crown land of Bohemia, was founded in the eighth century, and has a university founded in 1346. The university has about 3,500 students, of whom 2,000 are Bohemian and 1,500 German. There are 1,000 Bohemian and 500 German medical students. Formerly there were more medical students, but within the last few years the faculty was obliged to limit the number which may attend owing to the overcrowding of all Bohemia with doctors of medicine. The university is supported by the government of Bohemia, of whose population three millions are Bohemian and two millions are German. Outside of Prague the Germans have perhaps the greater share of wealth, owning the principal factories, which are in the northern part of the kingdom; but in the city four-fifths are Bohemian and one-fifth is German. There are also 20,000 Jews and a garrison of 7,000 men in the city. Prague is a very wealthy city. The streets and sidewalks are from three to five times as wide as in Berlin and cities of northern Germany, and the sidewalks are of grooved tiling, mostly glazed and often ornamental in color. In the matter of race, feeling at this time is quite bitter between Bohemian and German, and that it never totally abates is in evidence on all sides. Theatres must be Bohemian or German, as must all places of amusement, and boldly bear the title of one or the other; there is no intermixture of languages in the play or in the audience. The same obtains at the university and clinics, except that patients are distributed in equal numbers to German and Bohemian wards.

The German clinic in general surgery is under the direction of Professor Wolfer and the Bohemian under Professor Maydl. Likewise the gynæcological and obstetrical Bohemian is under Professor Pawlik, and the German under Professor Rosthorn. Material comes from the kingdom without as well as from within the city, and is quite abundant.

Rosthorn has thirty-two beds in the gynæcological department and does about one hundred and twenty laparotomies annually. His record shows seventeen hundred patients treated in the hospital and eighty-two hundred ambulant patients in 1897. He is a comparatively young man, and succeeded Schauta, now of Vienna, six years ago as director of the German Frauenklinik and professor at the university here. As in all the surgical and gynæcological clinics at Prague, I find doctors here from all parts of the world, but especially from the larger cities of America.

Wölfer is a very learned man, and when one is first shown all the detail of his antiseptics he falters; but when one sees Wölfer go through with it he realizes it is less cumbrous than at first appeared. He has a large amphitheatre covered with a glass dome, affording ideal light for operations, which he does before the class, and here he conducts his public clinics. He wears perfectly white sterilized buckskin gloves while lecturing, nor will he touch a patient except with hands so gloved; but before operating he removes these, washes his hands, and covers his arms, which are otherwise bare nearly to the shoulders, with stocking legs from the wrists to above the elbows; next he puts thin rubber finger condoms over his thumbs and index fingers, and over the hands he draws long buckskin gloves with thumbs and index fingers cut off short so as to expose the condom-covered parts. He wears a rubber apron from neck to feet, over which he puts a linen robe with short sleeves. Here for the first time in Europe I see heads of the operators covered. They wear small white linen caps without bills. When I inquire the reason for wearing the hand coverings, whether to protect operator or patient, Wölfer says it is to protect both. They protect the operator against infection from the patient, and, again, obviate the danger of conveying infection from one patient to another. Like Zweifel and Meyer, Wölfer claims that the sense of touch is not lessened with condoms over the fingers. All assistants wear gloves, also caps, even while removing a cancerous breast: but Wölfer alone wears condoms on the fingers. He also has thin rubber gloves, which he wears in making rectal and vaginal examinations and in doing intrapelvic and abdominal operations. The rubber gloves and condoms are kept in lysol, 0.5 per cent. solution, within covered glass jars, and in similar vessels are kept the buckskin gloves, but in pure glycerin with five per cent. of carbolic acid. Immediately before use, the gloves are removed and the carbolized glycerin is washed off in sterilized water.

Before operating, Wölfer and all assistants wash: 1st, the hands with soap for three minutes; 2d, the finger nails with brush for two minutes; 3d, the hands and nails in ninety-five-per-cent. alcohol for five minutes; 4th, the hands in sublimate solution for three minutes. In dressing wounds he has totally discarded iodoform, and instead uses a bluish-gray powder, a preparation of bismuth which is called "airol." This is dusted over or into septic or suspicious wounds in precisely the same manner as iodoform is utilized by other surgeons. He has a metallic suture, made of aluminium bronze, which is so pliable that he ties it with knots the same as silk without breaking: but he values this especially when nicety is required in co-

apting the skin by subcutaneous suture through the entire length of an incision, because this suture will not enmesh itself in the tissues and therefore can be withdrawn without disturbing union of the parts freshly united. In his pathological department Wölfer has many interesting specimens, and among them I noticed a cherry seed impacted in a Murphy button. This case is of special interest, the patient having been operated on by Wölfer with every indication of good recovery, when in ten days after the operation the patient died with great pain in the bowels, which lasted less than twenty-four hours. Wölfer's specimens are preserved so as to retain their natural color, after the method of Kayserling, Virchow's first assistant at Berlin. I observed a papilloma of the tongue, removed six months ago, which was preserved by this method; it looked as though it might have been cut out ten minutes before it was shown me. Kayserling's solution contains: potassium nitrate, 10 parts; potassium acetate, 30; formalin, 250; water, 1,000. The specimen was submerged in this solution and kept in an absolutely dark drawer or closet for twenty-four hours, and for the next twenty-four hours in absolute alcohol, in a dark or a light place; lastly it was placed in a glass jar filled with the following solution: potassium acetate, 10 parts; alcohol, 100; glycerin, 500; water, 1,500.

Wölfer's records are worthy of note. He, like Trendelenburg, keeps photographic records of his greater deformities at different stages, and also Roentgen-ray pictures. The records show that he treats about seventeen hundred patients within the wards and seven thousand ambulant patients yearly.

Maydl is professor of surgery in the Bohemian department of the university and director for that race in the surgical clinic at the hospital. He has one hundred and five beds, and his record shows seventeen hundred patients treated in his wards and eighty-two hundred and twenty ambulant patients in 1897. The professor is of small stature, nervous temperament, and quick motion, and he is a very brilliant operator, of large experience and practice. He is father of some important operations in surgery, one of which, on the jejunum, it was my good fortune to see him perform.

What Maydl lacks in physical stature is more than made even by his first assistant, Dr. Kukula, who is six feet three inches high, and weighs two hundred and sixty pounds, though yet less than thirty years old. He has travelled more in America than I have, he having devoted nearly a year in "doing" the States. He is acquainted with the better clinics and operators in our larger cities, and has visited San Francisco, Portland, and Seattle. He hunted in Yellowstone Park, and witnessed the Corbett-Fitzsimmons fight in March of 1897. He speaks English with zest, and, like all Prague, manifests delight in the acquaintance of an American.

Perhaps the most conspicuous figure in medicine at Prague is Professor Pawlik, in the Bohemian department of the Frauenklinik and also of the university. A native of Bohemia, he was educated at Vienna and remained twenty years in that city, the last ten of which he served as first assistant in the K.K. allgemeine Frauenkrankenhaus, where he taught more Americans than Germans. Pawlik has been in his present position at Prague nearly twelve years, and an idea may be had of the esteem in which he is held by patients when one goes with him through the wards. I noticed this in no other place to such an extent as with Pawlik. Many of his patients grasp his arms, hands, or wherever they can, and cling to him with fervor, kissing hands, arms, or garments with adoration. Their words I cannot understand, but the meaning of their acts is unmistakable. He does not appear to court or specially to repel this, but when he turns to speak or to give personal attention to a patient, which he does rarely, the joy of the patient is often expressed by tears, but always with smiles and happiness. Pawlik is more than six feet tall, has light hair and full beard rather closely cropped, and is at once the most courtly mannered and finest presence I have met in Europe. As an operator he is very dexterous. By appointment I went about two miles early one morning to see him introduce his catheter into a ureter. He held aloft his instrument, directly before introducing it, and told who he believed was not the inventor. When I began to get ready to see him introduce it his hand went up again, and I noticed that only a very short part of the long instrument was to be seen; the catheter was left in the right ureter for twenty-four hours. He was perhaps fifteen or twenty seconds in introducing it, possibly not half so long; at least I had not time enough to mark the duration or even the method of this interesting manipulation. In preparing for operating he has discarded sublimate solutions, and gives as his reason experiencing very unpleasant symptoms formerly when he washed his hands and arms before each laparotomy, repeated as often as two and three times the same morning. He washes his hands in (1) hot water and soap, (2) lysol, and (3) alcohol, scrubbing the finger nails and fingers with a stiff brush in each.

From Prague, almost due south two hundred and fifty miles, I arrived at Vienna, the Mecca of medical pilgrims from America for many decades, and of which an account will be given in a future paper.

J. Preston Miller, M.D.

OSTEOPATHY IN VERMONT.

To the Editor of the Medical Record.

Sir: Your timely editorial in regard to the bill before the New York legislature legalizing osteopathy should meet with a hearty response from every physician in the State and from every member of the legislature who desires to look back upon his career with satisfaction. I had the honor and misfortune to be a member of the senate of Vermont when a similar bill was passed, and I regret to know that it went through both houses with little opposition. It had back of it the most powerful lobby that any measure commanded during the whole session, and those members who could in any way be influenced in its favor were kept closely in hand and supported the bill vigorously. Very recently I had the pleasure of learning from a prominent citizen of Montpelier, where osteopathy flourished in 1896, that to-day it had gone the way of every other movement that had preceded it upon no foundation and depending for support upon the emotions of the people regardless of good common sense. I trust that the State of my nativity will not repeat the error of the State of my adoption.

H. L. Manchester, M.D.

Pawlet, Vt.

Kidney Tumors.—Küster (Moscow Congress, surgical section) recognizes three groups of malignant kidney tumors which are characteristic: 1. Carcinomata. Hard tumors, felt late in the disease on the border of the kidney, perforate the capsule at an early period, and move with difficulty. 2. Sarcomata. Particularly in childhood. They grow rapidly, soon forming large tumors, perforate the capsule late, and form inflammatory adhesions. 3. Struma suprarenalis. Attack but one pole as a rule, may remain stationary for years, then grow suddenly and rapidly. They are very malignant.—*Wiener klinische Rundschau*, January, 1898.

New Instruments.

A NEW NEEDLE FOR OPERATIONS ON THE UTERINE CERVIX.

By H. W. CHAPMAN, M.D.,

WHITE HALL, ILL.

The frequency with which needles are broken in operations on the uterine cervix is well known to all surgeons engaged in this kind of work. The object of the needle here described is to prevent such accidents. It is round, about one and one-half inches in length. The point is a combination of the Hagedorn and trocar, which penetrates readily and causes the smallest amount of bleeding. The anterior third only is tempered. The posterior two-thirds, being soft or without temper, in being pulled through the dense tissues at the upper angle of the cervical wound in repair of lacerations, bends instead of breaking, as does a tempered needle, frequently coming out bent in a reverse curve, when it can be caught in the needle holder and returned to its former shape by the surgeon's fingers.

Should it not be curved sufficiently for any suture, the defect can be remedied in an instant by the fingers; if curved too much for the next suture, it can be reduced in the same manner. It will be found useful in operations on the perineum, and in many other situations. I originally made two from ordinary darning-needles, which, notwithstanding the weakness of the elongated eye, have been through a very large number of operations without a break. They are now made for me by Messrs. Truax, Greene & Co., of Chicago.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending March 12, 1898:

	Cases.	Deaths.
Tuberculosis	181	113
Typhoid fever	6	4
Scarlet fever	187	5
Measles	362	11
Diphtheria	162	11
Laryngeal diphtheria (croup)	15	2
Chicken-pox	31	0
Cerebro-spinal meningitis	0	0
Pertussis	1	0
Parotiditis	2	0
Erysipelas	2	0

Mr. Leonard Hill on Sleep.—In *The Lancet* of the 29th of January Mr. Leonard Hill has an excellent paper on some of the phenomena of sleep. In the course of his remarks he says: "Indians have a wonderful faculty of going to sleep. They seem to shut themselves up at will with a snap-like slamming down the lid of a box with a spring, and they are fast asleep in a second. Many men of great intellectual power possess the same faculty noticeably—we may cite Lord Brougham and Shelley. Other men, like Johannes Müller, have only to take up the recumbent position immediately to fall asleep. It seems, then, that consciousness can be abrogated either by a repetition of monotonous stimulation or by the voluntary withdrawal from stimuli, objective and subjective. In the dullard to produce sleep it is necessary only either to withdraw all external stimuli or to harp on one. On the other hand, the overexcitable, intellectual man is kept awake not only by the intensity of the present but by the recollection of the past. He attempts to woo sleep, not only by withdrawing from external stimuli, but by monotonously reviewing over and over again some one memory picture. Thus Southey records: 'I listened to the river and to the ticking of my watch. I thought of all sleepy sounds, and of all soporific things—the flow of water, the humming of bees, the motion of a boat, the waving of a field of corn, the nodding of a mandarin's head on the chimneypiece, a horse in a mill, the opera, Mr. Humdrum's conversations, Mr. Proser's poems, Mr. Laxative's speeches, Mr. Lengthy's sermons. I tried the device of my own childhood, and fancied that the bed rushed round and round with me. At length Morpheus reminded me of Dr. Torpedo's divinity lectures, in which the voice, the manner, the matter, even the very atmosphere and the streaming candlelight were all alike soporific; when he who, by a strong effort, lifted up his head and forced open the reluctant eyes, never failed to see all around him asleep. Lettuces, cowslip wine, poppy syrup, mandragora, hop pillows, spiders'-web pills, and the whole tribe of narcotics would have failed—but this was irresistible: and thus, twenty years after date, I found benefit from having attended the course.'"

An Original Way of Doing a Vaginal Hysterectomy.—Dr. J. D. Arnold, before the California Academy of Medicine, October 16, 1897, reported a case in which a midwife, after having delivered a woman, thought she saw the head of a second child protruding from the vagina. She seized it with both hands, and violently delivered, as she supposed, a second child. What she did deliver was an inverted uterus, completely tearing it away from its attachments. The physician who was called in did nothing but tampon the vagina, and the woman made a complete recovery. No arteries were ligated, either *en masse* or singly.

Loss of Vitality in Metals.—It is a fact of comparatively recent discovery in chemical metallurgy that metals lose their vitality from repetitions of shocks and strains, and may be said, as the expression is, to suffer from fatigue—that is, they may be worked till their molecules fail to hold together, and then they are in a state of exhaustion. As is familiarly known, bars of tin, rods of brass, and wires of any metal will separate, owing to fatigue, if bent backward and forward continuously. By careful experiments, however, the fact is made to appear that a remedy exists for this condition of metals if the overstrain does not border on rupture, and this remedy is very much like that which is applied in the case of an overworked human frame, namely, rest. Feather-edged tools recover their vitality better than any others. Of course, the length of time required for this rest varies with different metals and the amount of strain to which they have been subjected. Hard metals, such as iron and steel, use up one and two years' time in the process; on the other hand, soft metals, like lead, retain their cohesive force longer and also require less rest. —*New York Sun.*

Responsibility of Medical Men.—The American *Review of Reviews* says that "Dr. Brouardel, the distinguished doyen of the Paris faculty, discusses, in the *Revue des Deux Mondes*, the important question of medical responsibility. In spite of the numerous references in satirical writers to the 'license to kill' supposed to be enjoyed by every son of Æsculapius, Dr. Brouardel has no difficulty in showing that the idea of medical responsibility is practically contemporaneous with civilization. Of course attempts have been made to get rid of the doctrine, in the interest of incompe-

tent practitioners. For example, in 1696 the Parliament of Paris declared that the responsibility for the effects of medical treatment rested with the sick person who chose the doctor, but some years later the same parliament condemned certain therapeutic methods, notably the transfusion of blood. They even issued a decree against the use of emetics; but this they had to rescind, for it was Louis XIV.'s favorite remedy for his frequent attacks of indigestion. In 1760 the Parliament of Bordeaux gave the enormous damages of 15,000 livres for a broken limb which had been badly attended to and had to be amputated. In England, in 1886, a doctor was acquitted, although he had given a purgative to a patient suffering from heart disease, who had died in consequence. Not to multiply instances, it is clear that legislators have failed to establish a firm basis of medical responsibility, and consequently the application of it has greatly varied according to the existing trend of public opinion."

Intubation.—The faults of tracheotomy were fully appreciated even in Malgaigne's time, as the following saying of his shows: "If I do honor to the real author of tracheotomy, what honor will he not deserve who will arrive to deliver us from it." Dr. Joseph O'Dwyer is entitled to all the honor and praise which a grateful profession can bestow for delivering it from tracheotomy.—J. H. SEVMORE, *Southern Practitioner*, November, 1897.

For Lack of Serum. — Rauchfuss affirms that no other city has so high a death rate from diphtheria as St. Petersburg, and avows that the cause is to be attributed to the short supply of antidiphtheritic serum.

Vital Statistics of the State of Maine. — The fourth annual report upon this matter has just been issued. The population of Maine in 1890 was 661,086. In 1880 it was 648,936, an increase in the decade of 12,150. The total number of births registered in Maine in the year 1895 was 14,762, and the number of deaths was 10,464, the natural increase of births over deaths thus being 4,298. Brain disease caused 1,323 deaths, and pulmonary tuberculosis 1,195. Of the zymotic diseases, diarrhœal diseases claimed 635 victims, while typhoid fever was responsible for 185. The zymotic death rate per 10,000 was 17.12. Among the persons whose decease occurred in 1895, four had reached or exceeded the age of one hundred years. Two of these were women, and two were men.

The Manner in which the Law Forbidding the Public Representations of Hypnotism Ought to be Modified.—Dr. Croq (*Journal de Neurologie et d'Hypnologie*, No. 15) gives the following conclusions: 1. Hypnotism presents great dangers for the subjects and for society. 2. It is absolutely necessary that the law should prevent the occurrence of accidents. 3. It is possible to simulate all the experiments of hypnotism. 4. In educating (training) an individual one can succeed in developing in him a state which has all the appearances of the waking state, and yet reduce the individual to a condition of complete automatism. 5. It is sometimes absolutely impossible for the most experienced expert to say whether or not an individual is under hypnotic influence. 6. The public representations of simulated hypnotism present absolutely the same dangers as do the public séances of actual hypnotism. 7. In order entirely to prevent these accidents, the law must forbid not only the real representations of hypnotism, but also the simulated ones.

Water from a Biological Point of View.—While formerly the quality of water as to purity was thought to be a matter of chemistry and determinable by chemical analysis, the whole tendency of modern research has been, as Dr. A. H. Veeder has shown in a paper read before the American Microscopical Society, to cause the question of the spread of disease through the agency of water to be regarded rather as a biological one. The danger is determined by the presence of certain living organisms and of conditions on which their continued existence depends, and not upon the quantity of them. The smallest possible inoculation may be fatal through their power of self-propagation, and there is no fixed dose. But if their growth is hindered by unfavorable conditions they may become harmless, no matter how many of them there may be. The purification of water depends on the destruction of these organisms or the production of conditions unfavorable to their growth. — *Appleton's Science Monthly.*

Health Reports.—The following statistics concerning small-pox and yellow fever have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended March 12, 1898:

SMALL-POX—UNITED STATES.

SOME OBSERVATIONS UPON MODERN SURGICAL TECHNICS, FROM AN ANALYSIS OF FOUR HUNDRED AND TWENTY-ONE OPERATIVE CASES AT THE CITY HOSPITAL.[1]

BY GEORGE EMERSON BREWER, M.D.,

ATTENDING SURGEON, CITY HOSPITAL; ASSISTANT DEMONSTRATOR OF ANATOMY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

IN response to an invitation from the chairman of your section, I shall take pleasure in presenting for your consideration and discussion this evening a few facts observed during the past three years in a more or less systematic study of wound infection at the City Hospital. In accepting this invitation, however, my pleasure is mingled in no small measure with a feeling of hesitation, when I consider my own limited experience in this department of surgery, and when I also recall the fact that it was in the hospitals of Boston that the first systematic and successful efforts were made which resulted in the revolution of surgical procedures in this country. The facts which I shall present are doubtless familiar to you all, and I must confess that in bringing this matter before you this evening I am actuated more by the selfish motive of learning something from your discussion than by the hope of presenting anything new.

With a view of explaining the reasons which led up to this investigation, permit me to state that the institution in which they were undertaken is the largest public hospital in our city, and in the class of cases admitted to its surgical wards it may be said to occupy a position midway between the very acute at Bellevue and the very chronic at the almshouse hospital. Owing, however, to certain customs and regulations regarding the transfer of patients from other municipal institutions to Bellevue and the City Hospital, our wards were to a large extent filled with patients whose state of nutrition was conspicuously vitiated by dissipation and disease. From a careful review of the histories, it was estimated by the writer that nearly eighty per cent. of all patients operated upon during the year 1895 were the victims of alcohol, syphilis, tuberculosis, diabetes, or Bright's disease.

It is not surprising, then, that during the first month of the writer's service, in May, 1895, of the forty-three cases operated upon for various injuries and diseases, not one aseptic case escaped suppuration, and only seven infected cases were rendered sterile by our operative procedures. As these results were far worse than any previously observed by the writer, even before the days of aseptic and antiseptic procedures, a rigid investigation was at once undertaken to account for this unfortunate and mortifying state of affairs. The methods which were employed during this period to prevent and overcome wound infection, as well as the experiments which were carried out during the following five months, with a view of improving our technics, were fully described in a paper presented by the writer to the Harvard Medical Club in May, 1896, entitled "Operative Surgery at the City Hospital, with a Preliminary Report on the Study of Wound Infection." Without entering into details, I may briefly state that the following was the method finally adopted:

Preparation of Patients.—A hot bath was given, when practicable, the day before the operation, followed by shaving the wound area and the application of a soap poultice for at least four hours; then the part was scrubbed for from five to ten minutes with green soap and hot water, followed by the application of a wet bichloride dressing, the latter to be made only by the head nurse in the ward, after thorough sterilization of the hands. Upon the operating-table the bichloride dressing was removed and the part douched with ether, alcohol, and sterilized water. The entire body was then covered with sterilized towels. The operator and all assistants were clothed in sterilized gowns; gauze caps were worn, to prevent infection from falling dandruff and from perspiration. The hands were scrubbed for five minutes with green soap and at least two changes of hot water, after thorough attention to the nails. They were then immersed in a saturated solution of potassium permanganate for one minute, in a saturated solution of oxalic acid for one minute, in a 1 to 1,000 solution of bichloride of mercury for three minutes, then rinsed with sterile water. The catgut was prepared by scrubbing with soap and water, by washing in alcohol and ether, and by prolonged immersion in a 1 to 2,500 solution of biniodide of mercury in chloroform. Silk and silkworm gut were sterilized by boiling. The instruments were boiled and then immersed in sterile water in sterile trays. The dressings, gowns, gauze sponges, caps, towels, etc., were sterilized for one hour. Accidental contamination of instruments, hands, and dressings was guarded against, when possible, by the appointment of a censor, whose duty it was to watch every step of the operation and at once to condemn any hand, instrument, sponge, or dressing which had by any accident come in contact with unsterilized material.

In spite of our efforts, however, at least thirty per cent. of our clean wounds continued to suppurate, until the plan of operating without an assistant was undertaken in a few selected cases, and suitably prepared catgut was used. No infection occurred in any of these cases, but the plan obviously could be adopted only for a limited class of patients. This reduced the percentage of infection to twenty (two stitch abscesses only occurring in the remaining ten clean cases). We were, however, still laboring under difficulties, as our operating-room was cramped, badly lighted, and badly equipped. We had none of the modern sterilizing apparatus, and our entire house staff was changed every six weeks. The report referred to closed with the statement that it was "the writer's intention to continue these experiments, and, if necessary, to inaugurate a series of bacteriological investigations, with a view of locating and removing any sources of infection which had, up to this time, escaped observation; after which it might be possible to gather some data which would help to solve the question of how much (if any) unavoidable suppuration might be expected in this class of cases."

[1] Read before the section on surgery, New York Academy of Medicine.

The work of our second year was devoted largely to bacteriological investigation. During this period the hospital was furnished with two new well-lighted and well-ventilated operating-rooms, fully equipped with the most approved modern operating-room furniture and fixtures. A complete sterilizing-room was added, furnished with three Sprague-Kny autoclaves of the latest model, together with instrument boilers, water sterilizers, and hand basins with pedal attachments; the whole placed under the direction of a thoroughly competent operating-room nurse, who with her assistants had the entire charge of the rooms and the preparation of all material.

The same methods were followed which I described before, with the exception that the catgut ligature and suture material was, in addition, boiled in alcohol under pressure, and the dressings, gowns, towels, etc., were submitted to three half-hour exposures to live steam.

During the first ten weeks of the writer's service in 1896, no case of infection occurred in a patient whose wound area had been clean before the operation. During the next ten weeks, however, four infections occurred, three stitch abscesses, and one case of fatal septic meningitis following an exploratory osteoplastic resection of the skull for traumatic epilepsy. It was then decided to inaugurate a thorough bacteriological investigation of our methods and materials. This investigation covered a period of about two months, and was carried out by Dr. Philip H. Hiss, assistant in bacteriology in the College of Physicians and Surgeons, and assistant bacteriologist to the New York board of health, and was fully reported in a paper read by us jointly before the surgical section of the New York Academy of Medicine, in March, 1897.

During this investigation numerous experiments were made in hand disinfection, the preparation of the patient's skin, the preparation of all ligature and suture material, and the sterilization of our dressings, gowns, towels, sheets, etc. Experiments were also made with a view of testing the possibility and probability of air infection. As a result of these experiments, three sources of infection were found to be possible in the technics hitherto employed. These were, first, from the dressings; second, from the hands of the operator and his assistants; and third, from the air. To remedy the first, one hour of continuous sterilization with live steam, under ten pounds' pressure, was adopted. To remedy the second, the Fürbringer method of preparing the hands was employed (which gave us the nearest approach to perfect sterilization), and, in addition, all assistants wore rubber gloves, which had been rendered sterile by boiling for five minutes and subsequently kept sealed in jars of bichloride. To remedy the third, no adequate means could be devised, although we adopted the plan of keeping our instrument trays and solutions under tents of sterilized muslin supported on wire frames.

By far the most important change in our technics which resulted from our bacteriological experiments was the adoption of the rubber gloves. This was first suggested to the writer by a former house surgeon who had seen them employed at the Johns Hopkins Hospital, in the service of Dr. W. H. Halsted. Although we had employed a number of well-known and highly recommended methods of hand disinfection, none gave satisfactory results when subjected to bacteriological tests; moreover, if the hands could have been rendered sterile by any of the methods employed, it is more than probable that they were very soon afterward contaminated from the air or from perspiration, the infectiousness of which no one will for a moment question. We found by experiments that rubber gloves could be rendered sterile by boiling for two minutes. At first, however, coarse gloves were used by the house surgeon, senior assistant, and operating-room nurse, the hands of the operator only remaining uncovered. This reduced the possibility of hand infection seventy-five per cent. A number of experiments were made, with a view of rendering practicable the use of very thin, closely fitting, pure gum gloves for the operator. As it was extremely difficult to draw these on the hand when wet, gloves were not used constantly by the operating surgeon until the autumn of 1897, when the following method was suggested to the writer by Dr. Charles McBurney, who was the first in our city, to the writer's knowledge, to adopt the systematic use of rubber gloves upon the hands of all connected with the wound during operation. The gloves were boiled for two minutes, then removed from the water to a large sterilized towel, and thoroughly dried by the operating-room nurse after thorough sterilization of her hands. The finger and thumb openings of the gloves were packed with sterile gauze and the gloves sealed until used. Before they were drawn upon the hand, the interior was dusted with starch powder which had been rendered sterile by dry heat. Gloves prepared in this way are worn with the greatest comfort and with practically no impairment of the tactile sense. At the close of our second year of investigation the following report was made:

"Of the 109 patients operated upon, 64 were infected at the time of operation, 43 were clean, and in 2 no incision was made. Of the infected cases, in 17 an attempt was made to establish asepsis and bring about healing by first intention or granulation without suppuration, and in 13 instances, or 76 per cent., we were successful. In the 43 aseptic cases a serious infection occurred in but 1 instance. If, however, we include the 3 cases of single-stitch infection, the whole number showing evidences of infection was 4, leaving 39, or 91 per cent., in which perfect asepsis was maintained."

These statistics, although markedly in advance of those during the first year, were still far from perfect, and in beginning again our work of investigation in January, 1897, it was with the firm determination to bring about if possible a still further improvement in our results.

As a sequence of our clinical and bacteriological investigations, and the resulting changes in our technics, we had practically excluded all sources of wound infection but three—the hands of the operator, the skin of the patient, and infection from the air. During the first five months of 1897, the same technics were employed as during the latter part of 1896, with the exception that a number of experiments were made with a view of rendering more complete the sterilization of the patient's skin, and of overcoming as far as possible air infection, which was thought to be responsible for a certain number of our suppurations.

The plan of rescrubbing the wound area of the patient on the operating-table, for one minute just before the application of the ether, in alcohol and sterile water, was employed. This was done by the house surgeon, after thorough sterilization of the hands, for which a freshly sterilized brush, sterile water, and a specially prepared sterile liquid soap were used. To avoid air infection, at the suggestion of Dr. Albert H. Ely, visiting gynæcologist to the hospital, the plan of douching cutaneous wounds with peroxide of hydrogen, just before the application of the sutures, was employed in a limited number of cases. This was done with a view not only of destroying any micro-organisms which might have fallen into the wound during operation, but also of disinfecting the track of the cutaneous sutures, and overcoming, if possible, infection by the staphylococcus epidermidis albus. A stitch infection occurred in but one instance when this method was employed.

A 1 to 1,000 solution of bichloride of mercury was employed in the same manner in a few cases, but was

later abandoned, both for theoretical reasons and for a practical demonstration of its uncertainty.

The use of formaldehyde for disinfecting septic wounds, as well as for sterilizing the air of operating-rooms and preventing infection in clean cases, was suggested, and a number of experiments were carried out with this agent. The first experiments with formaldehyde were made with glutol, or powdered formalin gelatin. My attention was first called to this substance by a paper upon the subject, read before the surgical section of the New York Academy of Medicine in 1896, by Dr. E. M. Foote, of New York, who advocated its use both in clean and in infected cases. Our first experiment with it was a striking one. The patient was admitted to the hospital in the spring of 1897, suffering from an extensive cellulitis of the foot. Free incisions were made on the dorsum under ether, and a number of necrosed tendons were removed. After several weeks of careful dressing, it was found that the presence of a number of other necrosed tendons and tendon sheaths prevented the healing, and an extensive sloughing ulcer remained. The patient was then advised to submit to another operation, and the question of amputation was seriously considered. As the patient refused a second opportunity for operative relief, the wound was dressed for two months with various solutions and applications, without improvement. Powdered glutol was finally applied after careful preparation of the wound. The suppuration ceased at once; healthy granulations appeared, rapidly covered, and finally completely buried the necrosed tendons and sheaths; the wound healed firmly. The patient was kept under observation for two or three months, during which period no trouble appeared from the buried tendons. Shortly after this experiment, during an excision of the wrist for tuberculous disease, it was discovered, after six of the eight carpal bones had been removed, that the disease had extended to the metacarpals. The operation was abandoned, with a view of allowing the patient to recover from the anæsthetic, when amputation of the arm would be advised. During the dressing my house surgeon suggested the use of glutol. Accordingly the cavity was freely dusted with the powder, and then thoroughly packed with gauze which had been impregnated with the agent. No reaction followed the operation, although the patient complained of considerable pain. At the first dressing, ten days after the operation, the wound was found to be filled with healthy granulations and absolutely free from discharge. The second dressing was removed ten days later, when the wound was found to be reduced to one-half its original size. A few weeks later it had completely healed. Although the patient was urged to remain in the hospital under observation, he insisted upon leaving, and shortly afterward began to use the hand. He returned several weeks later, thoroughly alcoholic, with the evidences of an acute inflammatory process at the site of the old operation. The wound was reopened, the two remaining carpal bones and the heads of several metacarpal bones were removed, and the wounds dressed as before. Healing was prompt and complete without suppuration, the patient this time remaining under observation for several weeks after complete healing, during which period he showed no evidences of trouble.

This agent was also used in a large number of other infected cases, with satisfactory results. Its use in aseptic wounds with a view of preventing infection was attempted in but a single instance. The patient was an old and enfeebled subject, probably tuberculous, and showed many evidences of malnutrition and bad circulation. The Bassini operation for inguinal hernia was done on both sides. Before the cutaneous wounds were closed, powdered glutol was freely dusted over the skin and subcutaneous tissues, and the wounds were then closed without drainage. No reaction followed. At the first dressing, on the tenth day, there was no redness or evidence of infection, but there was no union. One wound was opened and a large amount of semi-solid gelatinous material removed; the edges were allowed to fall together, the other wound remaining as it was. The final result was delayed healing, but there was no infection. The wound which had been opened healed first; both were solidly united in five weeks.

With a view of testing the antiseptic value of formaldehyde gas, the following experiment was undertaken: A room was selected in the hospital, the air of which was known to be badly infected. The capacity of the room was about twenty-eight hundred cubic feet. In this room were placed a large number of test tubes containing gauze soaked with pus taken from suppurating wounds in the wards; also tubes containing Subtilis spore threads obtained from the pathological laboratory of the College of Physicians and Surgeons. These were placed at a number of levels and more or less completely embedded in masses of gauze, towels, and sheeting. The room was then closed as tightly as possible, and formaldehyde gas passed from the Trillat generator through the keyhole in the door. The gas was turned on at 2:40 P.M., and allowed to flow in for one hour. The room was opened three hours later. The various pieces of pus-soaked gauze and the spore threads were then transferred to bouillon tubes; also scrapings from the floor and side walls, window sills, and board shelves. These were sent to Dr. Hiss for incubation. No growths were obtained from any of the tubes thus inoculated. These experiments demonstrated conclusively the powerful antiseptic properties of formaldehyde gas.

Our attention was next directed toward the use of some other preparation of formaldehyde, which would not exhibit the disadvantages of glutol. The preparation sold under the name of formalin was employed in a number of experiments. The first experiments were in the direction of hand disinfection. The following plan was adopted: The hands, after thorough attention to the nails, were scrubbed with green soap and hot water for five minutes; then scrubbed for three minutes in a 1 to 100 solution of formalin; after which they were immersed in sterile water. Six culture tubes were inoculated from the nail scrapings and interdigital scrapings from three of my house staff after preparation of the hands in this manner, with the result that five of the tubes remained sterile and one tube only showed growth. Later nine tubes were inoculated in the same manner, a 1 to 50 solution of formalin being used, with the result that no growth occurred in any of the tubes. As a result of these experiments, this method of hand disinfection was adopted, and was used by the writer not only in his hospital service but in private practice, until the final adoption of sterilized rubber gloves.

The next series of experiments was in the disinfection of acutely septic wounds. One of the first patients presented a very extensive and particularly foul perirectal suppuration. The wound was opened under chloroform anæsthesia, thoroughly curetted, irrigated with a 1 to 300 solution of formalin, and packed with gauze wet in a 1 to 50 solution of formalin. The first dressing was made two or three days later, when the wound was found to be perfectly clean. Repacking, however, with the same agent caused great suffering.

The next experiment was with an angry cellulitis of the leg; the procedure was practically the same, packing with gauze wet in a 1 to 100 solution of formalin. Result, a clean wound with considerable pain. Later, a wound of excision of a large carbuncle on the back was dressed with a solution of 1 to 300 of the formalin. Result, clean wound with moderate pain after

second dressing. A large perinephritic abscess was treated in the same manner with 1 to 100 formalin gauze. Result, clean wound with excruciating pain after second packing, which lasted two or three hours. A large intraperitoneal appendicular abscess was irrigated and then lightly packed with formalin gauze, 1 to 100, with the result that the cavity was not rendered aseptic. Seventeen other infected cases of about the same class were treated in this same manner, making twenty-two in all. Of this number, eighteen were known to have been rendered aseptic; in three the suppuration persisted; and in one instance the records failed to note the result. Of the three in which suppuration persisted, one was the appendix case referred to above. One was an extensive cellulitis of the thigh necessitating several incisions; at the first dressing pus was found in only one of the incisions. The third case was a necrosis of the superior maxilla with antrum disease; a large amount of dead bone was removed and the antrum packed; the nasal foramen, however, was patent.

From an analysis of these cases, I think it may be fairly stated that solutions of formaldehyde exert a marked germicidal effect when brought into contact with septic wounds, but that its use has the disadvantage of producing considerable temporary pain. This factor led us to discontinue its use in subsequent dressings, and the plan finally adopted was to employ the agent in the strength of 1 to 50 while the patient was under an anæsthetic, in the hope (which was generally realized) that the wound would be sterile at the first dressing, after which only plain sterilized gauze was employed for packing.

While these experiments were in progress, we were disappointed in finding that our records of aseptic cases operated upon were not showing the same improvement. The technics which we employed during the first five months were the same which we have described, and I can conscientiously state that they were carried out to the letter. In spite of our efforts, however, six clean operative wounds became infected during the first five months of 1897. Two of these infections were easily explained, as the patients were both operated upon during one afternoon and each wound was drained by a small strip of rubber protective tissue, which we were afterward led to suppose had not been thoroughly sterilized. Three of the remaining four cases were simple stitch infections, practically without symptoms and in no way interfering with the ultimate recovery of the patient. The sixth case was a virulent and rapidly fatal septicæmia, following an operation for hernia, in a young and apparently perfectly healthy patient. Immediately after this unfortunate event, the house staff, operating nurse, and one or two who witnessed the operation were called together, and careful inquiry was made in regard to every step of the operation and the preparation of all the material used, without eliciting any clew which would lead toward the discovery of the cause or revealing the smallest error in our technics on that occasion. It was therefore decided that some energetic measures must be undertaken to overcome the possibility of air infection, which we knew to be present in our operating-room, as well as the probability of hand infection from the operating surgeon. As our experiments with formaldehyde had been so successful in septic cases, I determined to follow the simple plan of wiping the divided tissues in each aseptic case with gauze sponges wet in a 1 to 50 solution of formalin just before the wound was closed, of inserting a small gauze drain at one or both angles of the wound, and of applying several layers of wet formalin gauze next to the skin, and then the usual dressing of sterilized gauze and cotton. Shortly afterward the regular use of rubber gloves by the operator was adopted, which removed all possibility of infection from bare fingers. This plan succeeded admirably in preventing infection. Not a single case of infection of a clean wound occurred in our service during the remaining four months.

A brief review of the results obtained during the three years would show that during our first year 147 cases were operated upon; in 38 of these the wound area was presumably free from infection at the time of operation; of these, 15 suppurated and 23 remained aseptic; ratio of infection in clean cases during 1895, 39 per cent. Second year—total number of operations, 109; clean cases, 43, of which 4 became infected and 39 remained sterile: ratio of infection in clean cases during 1896, 9 per cent. Third year—total number of operations, 165; clean cases, 83, of which 6 became infected and 77 remained clean; ratio of infection in clean cases during 1897, 7 per cent. If, however, we divide the service of the nine months during the last year into two periods—one of five months before the systematic use of formalin and gloves in clean cases, the other of four months after the adoption of these methods—the first period will show that of 40 clean cases operated upon 6, or 15 per cent., became infected; while, during the last four months, in 43 clean operations there was no case of wound infection.

From a careful view of the facts presented by this investigation, I think we are justified in urging the necessity of what might be termed an exaggerated system of surgical technics when dealing with the class of cases in which resistance to infection has been markedly diminished by dissipation or disease. When, in addition, we are obliged to carry out our operative work in an atmosphere which is badly infected, the possibility of air infection must be guarded against by the use of antiseptic measures in addition to our aseptic technics. That in formaldehyde we have one of the most powerful disinfecting agents which can safely be used in surgery, and that the systematic use of sterilized rubber gloves by all taking part in an operation, will, in connection with an otherwise perfect system of technics, be found to be of the greatest value by those caring for this unfortunate class of patients, seem to be established.

TREATMENT OF CHRONIC DISEASES OF THE HEART IN THE LIGHT OF ROENTGEN RAYS.

BY THEODOR SCHOTT, M.D.,

BAD NAUHEIM, GERMANY.

SEVEN years ago I published in this journal[1] a paper concerning my late brother's and my treatment of chronic diseases of the heart by means of baths and therapeutic exercises. Since that time I have had the gratification of observing that the new method has attracted the attention and insured the approval of medical men abroad, not only in Russia, Sweden, Holland, Denmark, Belgium, etc., but more especially in England, the United States, and those countries where the English language is spoken. This was greatly owing in England to the treatises published by Bezly Thorne, Sir William Broadbent and John Broadbent, Wethered, Bowles, Saundby, etc., and to the discussion drawn forth by Sir Thomas Grainger Stewart at the meeting of the British Medical Association at Carlisle. In the States attention was drawn to the method by the publications of Babcock, Osler, Rives, and others, and interest in it was kept alive by the discussions at medical meetings in In-

[1] "Balneo-Therapeutics and Mechano-Therapeutics Applied to the Treatment of Chronic Heart Diseases," MEDICAL RECORD, February 14, 1891.

dianapolis, Baltimore, Philadelphia, Buffalo, etc. Among the many patients and practitioners coming to Bad Nauheim from all countries I have especially noticed the steadily increasing number of sufferers and medical men from the United States. The latter especially have come to Nauheim partly to undergo treatment themselves, partly to study the system of treatment in a practical manner. I most willingly comply with the wishes of many of these colleagues to report my experiments with the Roentgen rays, with the view of furnishing an evident incontestable proof of the effect produced on the heart by this therapeutic method.[1]

FIG. 1.—Boy (Thirteen Years) before Therapeutic Exercises.

The fact that measuring the heart muscle post mortem, which has served till now as a basis for judging of the increased size of the heart, is wholly unreliable and, further, the fact that the physical means of diagnosis in the living are insufficient, have given rise to another fact, that many colleagues, though through observations and experience perfectly convinced of the therapeutical effects, have been unable to account satisfactorily for the immediate effect of the baths and exercises. Some were even so sceptical as to doubt the effect on the heart and attributed the undeniable apparent reduction of its size to an increased overlapping by the lungs. This supposition, as I have demonstrated verbally and by writing, can be easily refuted. After the exercises, for instance, the apex beat works visibly and palpably upward and inward, while the diaphragm rises simultaneously and the margins of the lungs—behind, above, and below—remain unchanged. But it is evident that even this rational refutation has not been sufficient to remove in some minds every doubt regarding this subject.

The question was in this state when there intervened the stupendous discovery of Roentgen. As soon as the possibility of rendering the heart's action visible by means of skiagraphs or the fluorescent screen was demonstrated I commenced my experiments, in which I was efficaciously supported by Professor Koenig, director of the physical institute at Frankfort-on-the-Main and by some colleagues of mine, to all of whom I am much indebted. In the beginning of my experiments I selected by preference children of nine to fourteen years of age, because at that period the technique was not yet sufficiently perfected to insure a quite satisfactory reproduction of the organs of adults.

As the object of the hereinafter-described experiments is to ascertain the changes of the dimension of the heart produced by baths, exercises, etc., it must be taken into account that the apparent size of the heart varies according to the relative distances between the Crookes tube, the patient, and the photographic plate. The more the distance between these three is reduced, the larger the reproduction of the heart will appear. It follows therefrom that if we want to exclude every mistake from this source it will be indispensable always to maintain the same relative distances for each experiment with the same individual. This can be managed in the following manner: The patient lies on his back in a perfectly horizontal position, stretched out on a large table; this position is exactly marked by means of outlines of the figure, so that when the experiment is repeated the former position can be accurately resumed. The tube is fastened always in the same spot beneath the table. The photographic plate in the first experiments rests on a support, and afterward to give a still steadier hold is screwed to four arms firmly fastened to the table. The photographic plate is placed as near as possible to the body, but still at such a distance that the respiratory movements cannot touch and disturb it. The distance between tube and plate has always been one-half metre, experience having shown that this distance reproduces the natural size of the heart. By raising the head moderately I obtain quiet respiration. I need not add that during the whole experiment the person is admonished to keep as motionless as possible. I have recently placed on the nipples small pieces of lead which, as this metal is but slightly penetrable by x-rays, appear as dark points on the skiagraphs as well as on the screen. By this method one obtains a better control of the effect, especially with regard to the physiological movements of the heart.

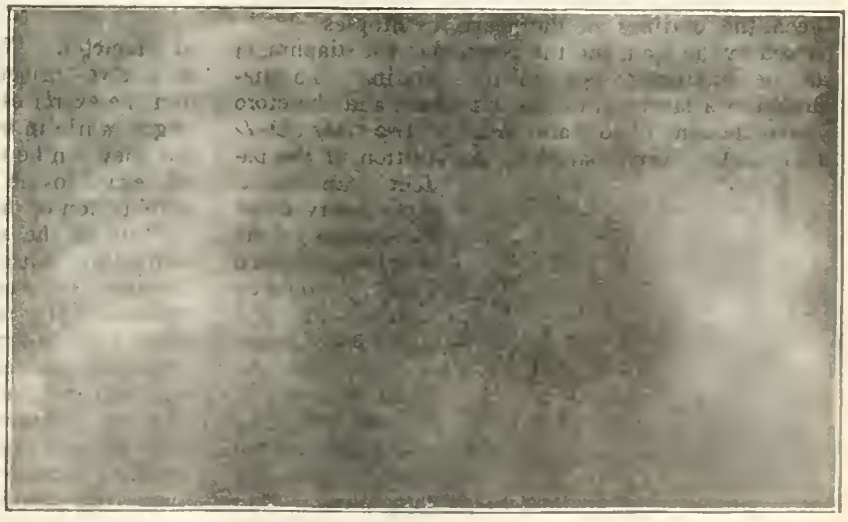

FIG. 2.—Boy (Thirteen Years) after Fifteen Minutes of Therapeutic Exercises. The patient rested fifteen minutes before the second skiagraph was taken.

In order to demonstrate the effect of the therapeutic

[1] A special article concerning the treatment of chronic diseases of the muscle of the heart will be published by me in a short time.

exercise I select one of the earliest experiments. A boy, thirteen years of age, was extremely weak and anæmic. Percussion showed an evident dilatation of

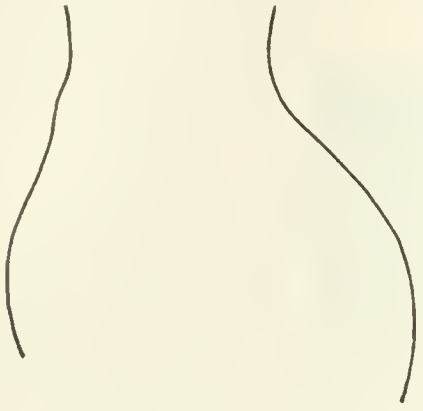

Fig. 3.—Before Therapeutic Exercises. (Diagram from Fig. 1.)

the heart. Two skiagraphs were taken, one before and the other fifteen minutes after a quarter-hour exercise with middling resistance. The second skiagraph demonstrated well the change of the size of the heart in such a way that it became evident the heart had contracted strongly on both sides. The round form of the heart had changed to a flat one and, as some colleagues justly observed, the heart which had had the form of an orange had assumed that of a lemon. This was most evident on measuring the size of the heart, as shown on the fourth rib: before exercises, 10.4 cm.; after exercises, 9.2 cm.: that is to say, the heart had contracted 1.2 cm., equal to one-half an inch.

In earlier publications[1] my brother and I have demonstrated how by these means the tonic effect on the heart is insured. Promptly and in an unrefutable manner the reduction of the heart can be demonstrated *ad oculos* by means of the fluoroscope. For this purpose I fixed on the fluorescent screen a thin layer of gelatin and designed thereon the outlines of the heart, before the exercises with black ink, and after with red ink. (In the figures broken lines are substituted for the red ones.) If you put the person between the tube and screen, the outlines of the heart, the nipples marked by the lead, and the position of the diaphragm can be distinctly seen on the gelatin. The diaphragm oscillates a little up and down, and therefore I have thought fit to mark this with two lines (*D–D* in Fig. *A*). Every change of the position of the patient can be at once observed by the change of the position of the black points (lead), and thus the small pieces of lead give the certainty that the position of the person remains unaltered during the experiment.

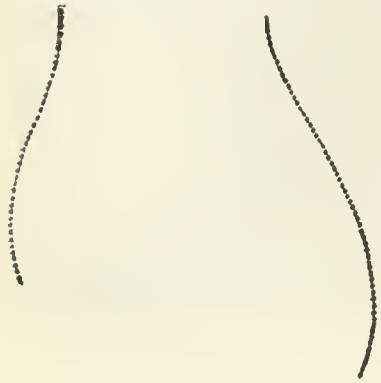

Fig. 4.—After Fifteen Minutes of Therapeutic Exercises. Patient rested fifteen minutes before second skiagraph was taken. (Diagram from Fig. 2.)

The next diagram (Fig. *A*) is that of a girl, thirteen years of age, who suffered from weakness of the heart subsequent to a rheumatic fever. The horizontal diameter at the level of the nipples is: before exercises, 11 cm.; after exercises, 9.4 cm.; equivalent to a reduction of 1.6 cm. At the same time the diaphragm has risen a good deal, from *D–D* to *D'–D'*, a further proof of the reduction of the size of the heart. The reduced size of the heart, the lungs remaining normal, will now permit the diaphragm to move upward, while if the lungs were distended by the exercises, the heart remaining unchanged, the diaphragm would be pressed downward. But just the contrary takes place and is made evident by the fluoroscope. In the case of a girl, fourteen years old, suffering from dilatation of the heart, the effect of an insufficiency of the mitral valve, I had occasion to demonstrate by means of the screen at Würzburg, in presence of a large number of physicians and students, the reduction of the size of the heart after one-half hour of therapeutic exercises.

The effect of a Nauheim effervescent bath upon a girl, fourteen years of age, I have already described in the *Deutsche medicinische Wochenschrift*, No. 14, 1897, and have made it evident by means of the reproduction of a skiagraph. In order to ascertain the effect of the bath distinctly and subject to no other influence, I had the child carried to the bath and after the same transported back directly to the table. The heart contracted nearly one centimetre in the horizontal diameter. The immediate effect of the bath is, as I have formerly stated, not quite so marked as after the exercises, but it has the advantage of lasting longer, while in favor of the exercises it may be stated that they can be used repeatedly in one day and without regard to the place. The diagram (Fig. *B*) is a reproduction of the last-mentioned skiagraph.

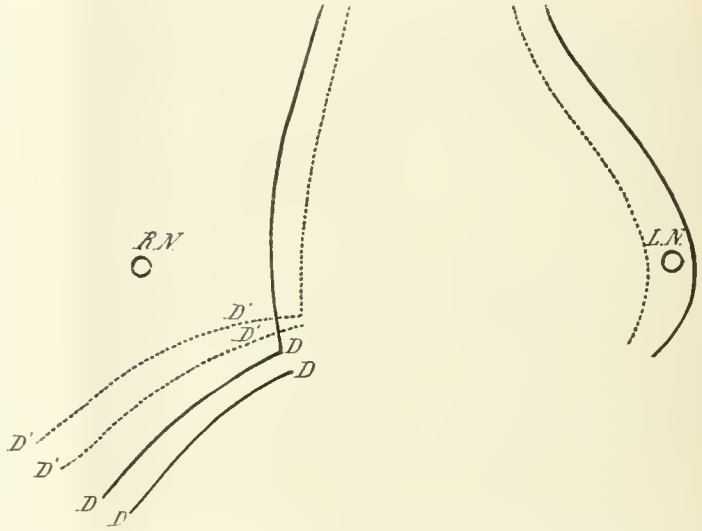

Fig. *A*.—Outlines of the Heart before Exercises. *D*, *D*, Diaphragm before exercises; *R.N* and *L.N*, right and left nipples. (Dotted lines, outlines of the heart after exercises; *D'*, *D'*, diaphragm after exercises.)

While in the above statements I have proved the contracting, that is to say, the tonic effect of baths and exercises, it can easily be shown, on the other hand, by application of *x*-rays, how overstraining produces dilatation, *i.e.*, weakening of this organ. For this purpose I repeated some experiments which I had made eight years ago and detailed before the meeting of the Society for Internal Medicine at Vienna. They were based on my having caused people to wrestle until the breathing became very short. Tachycardia, often combined with arrhythmia and dilatation of the heart, was the immediate consequence. The following skiagraphs show the effect upon a boy, twelve and one-half years old, of strong muscles, in perfect health. The small pieces of lead greatly facilitate the observation of this process. Fig. 5 was taken before the wrestling and Fig. 6 after ten minutes' wrestling and three minutes' rest. This rest served to reduce the movements of the heart and the diaphragm. The dia-

[1] Medical Record, February 14, 1891.

phragm is moved downward and the heart shows an enlargement in its vertical and principally in its horizontal diameter. Thus, for instance, I could find at the level of the fourth rib an increase of 1.3 cm.

The dilatation of the heart can be accelerated if, before wrestling, we compress the belly by means of a

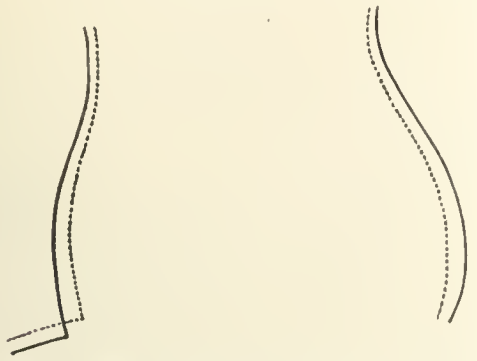

Fig. 3.—Before the Bath. (Doted lines, after a Nauheim effervescent bath, 88° F., ten minutes in duration.)

strap beneath the ribs, which, as it is generally known, forces the heart to work with more than usual strength. With the view of preventing any injury to the health I never allowed the boys to wrestle longer than three minutes. Before this time palpitation and dyspnœa became evident. At the end of this process, as might

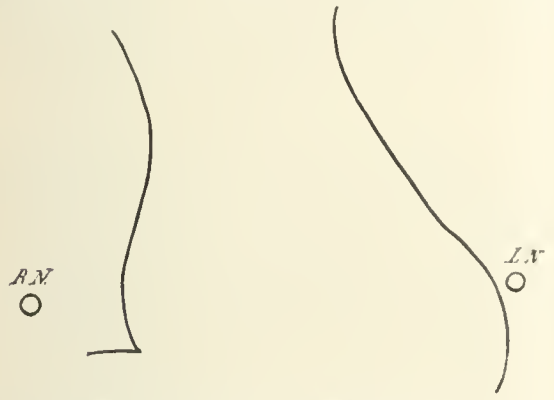

Fig. 5.—Outlines of the Heart before Wrestling. *D*, Diaphragm before wrestling; *RN* and *LN*, right and left nipples.

naturally be expected, the right ventricle showed at first more marked dilatation, viz., 1.3 cm., while the left one was dilated only 1 cm. But the left ventricle returns more quickly to its normal state, and thus we see after some time, as after the taking of a skiagraph—an operation which formerly required some time—that

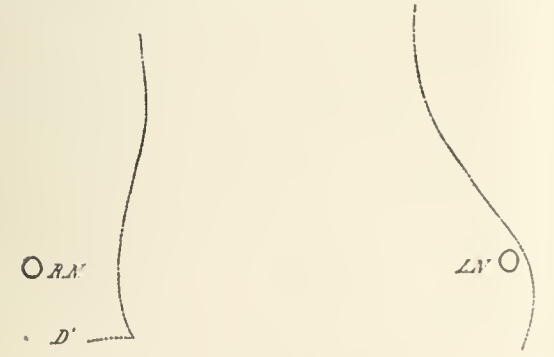

Fig. 6.—Outlines of the Heart after Ten Minutes of Wrestling. *D'*, Diaphragm after ten minutes of wrestling; *RN* and *LN*, right and left nipples.

the left continued dilated while the right one had recovered its original size.

In a paper on overstrain of the heart [1] I reported several years ago some cases of heart disease arising from overstrain. In the course of recent years I have had under my treatment an increasing number of patients in whom excessive bicycling has produced an injurious effect upon the heart in the form of dilatation. I could, indeed, demonstrate through the person of a colleague of mine, with the help of Roentgen rays, that bicycling on bad roads or against a strong wind easily produces dilatation of the heart.

In conclusion I may say that these photographs and diagrams of the fluoroscopic image are not only a valuable addition to physical diagnosis, but they at the same time show in a most reliable way the process which takes place directly in the heart. Through its means we recognize distinctly how baths and therapeutic exercises stir the heart to make powerful contractions, that is to say, exert a tonic effect upon the heart. On the other hand we see that overexertion dilates the heart and leads to a *debilitas cordis*, the latter of which is likely to be the cause of a chronic weakness of the heart, with all its ruinous consequences.

The relative signification of therapeutic exercises and of such physical acts as wrestling, running, climbing, etc., which may lead to overexertion may be best explained in the plain words which I used before: "Unsystematic exercises weaken the heart; systematic exercises, on the contrary, strengthen the heart."

I hope that my colleagues abroad will after an attentive perusal of this paper convince themselves of the correctness of my statements, for "seeing is believing."

THE SYMPTOMATOLOGY AND TREATMENT OF THE COMMON CLINICAL FORMS OF LITHÆMIA.

By ALBERT C. BARNES, A.M., M.D.,

ASSISTANT IN CLINICAL MEDICINE, PHILADELPHIA POLYCLINIC.

In current medical literature, lithæmia in its various aspects receives a great deal of attention. Recent writers, in dealing with this subject, recite cases which so strongly suggest errors in diagnosis that the tendency of clinicians of the widest experience and best training is to be sceptical in regard to what has been variously termed uric-acidæmia, lithæmia, irregular gout, etc. Indeed, so strong is this tendency that there is danger of going to the other extreme in classifying as intrinsically organic many affections which there is abundant reason to suppose are due to poisons circulating in the blood.

The clinician's rôle in the investigation of lithæmia is peculiarly difficult, because, looked at from whatever standpoint, a vast amount of conflicting evidence confronts him. Physiological chemists, pathologists, and clinicians secure irreconcilably different results when working with the same subject. However, sufficient evidence has been obtained to justify the statement that lithæmia is a result of faulty nitrogen metabolism, and our knowledge on the subject must come from the analytical chemistry of the blood and of the excretions. The object of the present article is to call attention to a class of cases of very common occurrence both in dispensary and private practice, which have at least one point in common—*i.e.*, their rebelliousness to ordinary treatment. These cases, while presenting symptoms referable to several different organs and structures of the body, are probably common in their etiology, and are undoubtedly benefited by the treatment detailed below. The term lithæmia, in the sense in which it was originally employed by Murchison, can be used to embrace these cases.

Pathology.—In spite of the fact that the pathology of lithæmia has been recently investigated and made the subject of extensive report by such men as Neus-

ser, Von Noorden, Leveson, Klemperer, and Kolisch on the continent, Duckworth, Garrod, and Haig in England, and Rachford, Futcher, and others in this country, comparatively little is definitely known on the subject. Upon one fact, however, all investigators whose work is entitled to serious consideration agree: and that is that uric acid has very little, if anything, to do with the symptoms of lithæmia. Uric acid is physiologically inert; its injection and ingestion in the lower animals are unattended with toxic symptoms. It is probable that the agents responsible for the symptoms of lithæmia are the xanthin bases, one of the three groups of alloxuric bodies, of which the hypoxanthin bodies and uric acid make the other two groups. The alloxuric bodies are probably all due to the catabolism of the nucleins of the body. Horbaczewski's well-known work is conclusive as to that origin of at least one of these groups (uric acid), but it is not yet so certain as to the origin of the hypoxanthin and xanthin bases. It is true, however, that when a faulty nitrogen metabolism takes place, as is the case in lithæmia, the formation and consequent excretion of the alloxuric bodies are increased. The elimination of these bodies takes place by means of all the emunctories, but principally by the kidney; consequently the urine contains an excess of these bodies in lithæmia. Kolisch has shown that in gout, undoubtedly very closely allied to certain forms of lithæmia, the xanthin bases are increased and the uric acid is diminished—facts which Futcher's recent work has confirmed.

Rachford asserts that after certain lithæmic paroxysms he has always been able to demonstrate in the urine the presence in excess of heteroxanthin and paraxanthin (two members of the xanthin group), and to these two alkaloids he ascribes as causative factors the symptoms of lithæmia. Furthermore, this investigator has induced attacks in the lower animals, very similar to those of lithæmia, by injecting heteroxanthin and paraxanthin. It is probable, however, that other of the xanthin bases as well as certain leucomains will be found to be etiologic in these conditions. That heteroxanthin and paraxanthin are responsible for some forms of lithæmic paroxysms, there is but little doubt, yet it is unreasonable to suppose that symptoms so manifold as those of lithæmia are caused by these two bodies alone. Briefly, then, the toxic symptoms of lithæmia are due to the circulation of the xanthin bases in the blood, while the pains so common among lithæmics are probably due to the mechanical irritation of uric-acid salts upon the peripheral nerve endings.

Symptomatology.—The symptomatology of lithæmia as described in this article is made up from the clinical records of a large number of cases occurring principally in dispensary practice among the poorer classes of people. These symptoms, while seemingly diverse and referable to many organs and tissues, can be arbitrarily arranged in several groups. It is a curious fact that lithæmia in the same individual may manifest itself as a paroxysm, the symptoms of which are largely referable at one time to one organ, and at another time to some other and distant organ. For instance, a lithæmic may have at one time a typical attack of what is ordinarily termed "biliousness," while the next paroxysm will be one of migraine, unattended with symptoms indicative of disturbance of the stomach or liver. It is the writer's opinion that the clinical records of most dispensaries would reveal many cases classified as chronic rheumatism, nervous dyspepsia, chronic gastric catarrh, migraine, neurasthenia, anæmia, and various forms of headache, in which the real etiological factor—a lithæmic habit—has not been suspected. This is particularly true of a large proportion of cases of very common occurrence, in which the stomach and intestines present symptoms of chronic indigestion. These patients also are depressed mentally, are irritable, often irascible, and at times melancholic. Certain functional disturbances of the stomach, liver, and intestines are caused by a lithæmic condition, and it is not the case, as is often maintained, that the general symptoms of lithæmia are due to functional or organic disorders of the above-mentioned organs. In other words, lithæmia stands in the relation of cause and not effect. There can be no more convincing proof of this statement than the fact that the stomach, liver, and intestines may be appropriately treated without effecting a change in the general symptoms.

On the other hand, antilithic treatment is followed by prompt disappearance not only of the supposedly secondary symptoms, but also of those due to disturbances of the stomach, liver, or intestines. Furthermore, in these cases I have repeatedly been able to precipitate true paroxysms of lithæmia by a nitrogenous diet, at the same time administering remedies to restore the function of the above-mentioned organs.

Gastro-Enteric Symptoms.—The gastro-intestinal symptoms of lithæmia are divisible into two general classes. The first class comprises many cases ordinarily designated nervous dyspepsia, gastralgia, or gastrodynia, in which the symptoms manifest themselves continuously, without periodic intensifications. The second group comprises those in which the symptoms, while present more or less constantly, occur in periodic exacerbations, constituting what are generally called "bilious attacks." These cases are commonly classified as chronic gastric catarrh or indigestion.

The nervous element in the first-mentioned class of cases is the most characteristic and striking feature. These patients are generally ill nourished, weak, sometimes sallow, with an appearance bespeaking general wretchedness. The appetite is variable, although generally good, with a craving for unusual articles of food. The digestion of the food is apparently normal, there being freedom from distressing symptoms of acid dyspepsia. The bowels are usually costive.

The nervous features of the case require special consideration. Pain in the epigastric region while the stomach is empty is always present. Its intensity varies from a slight uneasiness to a degree which leads to exhaustion. Headaches of neuralgic character—to be described later—and dysmenorrhœa are of common occurrence. In one of my cases the dysmenorrhœa was supposedly due to an anteflexed uterus, and the cervix was forcibly dilated: but painful menstruation continued for more than a year, until relieved by antilithic treatment. These patients complain of general nervousness, have frequent attacks of palpitation of the heart, suffer from insomnia, and are subject to periods of profound mental depression. Exaggerated cases of this nature present the clinical picture of neurasthenia, and, indeed, are most commonly treated upon that basis. Particular care, however, has been taken to exclude the class of cases described by De Dominicis[1] and commonly called oxaluria, but which are in reality cases of neurasthenia. Briefly stated, these latter patients suffer from dyspepsia, constipation, indisposition, apathy, irritability, hypochondria, loss of muscular and sexual power, and emaciation. Examination of the urine and results of treatment will bring out the points of difference necessary to a differential diagnosis. In lithæmic cases the urine is high colored, of a specific gravity ranging from 1.022 to 1.030, and generally strongly acid, while it contains a striking excess of urates and very few, if any, oxalates. The treatment of neurasthenia by rest, tonics, stimulants, and a meat diet yields good results, while such measures are of no value in lithæmia.

[1] Wiener medizinische Wochenschrift, vol. iv., Nos. 25 and 26.

The second group of cases, presenting symptoms commonly ascribed to chronic gastric catarrh, is of very frequent occurrence. The characteristic feature is that, while the symptoms manifest themselves in more or less severity, there are periodical exacerbations which prostrate the individual for periods varying from one to several days. The generally accepted view regarding the cause of these cases—namely, that the organ primarily at fault is the stomach, which by long disturbance secondarily involves the liver, thus causing the explosion of symptoms termed "biliousness"—is erroneous. It is true the stomach and liver are disturbed; but the etiological agents which are responsible for the disordered functions of these organs are, probably, certain toxins in the blood.

The individuals presenting the second group of symptoms are of typically lithæmic habit. They are generally well nourished, in the prime of life, and given to excesses in food and drink. The symptoms referable to the stomach appear soon after eating. There are pain and a sensation of fulness in this region, with evidences of slow digestion and acid eructations. The pain is generally more severe than in the regular forms of acid dyspepsia, and sometimes amounts to cramps, the pains shooting backward from the stomach. Nausea, vomiting, flatulence, and constipation are often present. Dr. David D. Stewart tells me he has found that pains variously ascribed to the stomach, intestines, appendix, etc., are very often due to the mechanical irritation of uric acid in the kidneys. Such an origin of the pains in the second group mentioned above is highly probable.

Soon after a meal the patient becomes dull, apathetic, loses the power of concentration, is mentally depressed, wants to sleep, and has dull, unpleasant feelings in the head. Vertigo is not uncommon, and hemorrhoids are present in a considerable proportion of cases. In many of these there is a history of what are commonly called rheumatic pains. These disorders partake of the nature of dull aches or sharp pains in the back and legs, with occasional attacks of quite pronounced pains in one of the joints in some cases, during which attacks the dyspeptic symptoms commonly disappear.

The periodical exacerbations of the digestive symptoms, occasioning attacks of biliousness, are particularly distressing. The frequency of the attacks varies; an average interval is from four to eight weeks. In women they are very liable to occur just previous to, during, or immediately after menstruation—a very significant fact, since it has been observed that the toxic agents which are probably the cause of the paroxysms are found in larger quantities in the urine at these times. The attacks sometimes resemble true migraine. They develop in the course of one or two days, during which the individual feels wretched. The initial symptoms are generally dull pains in the head, apathy, loss of appetite, closely followed by the nausea and vomiting which compel the individual to seek absolute rest. The nausea and vomiting constitute the most striking objective symptoms, while gastric pain is almost invariably present. Fever, varying from 100° to 103° F., and dyspnœa are to be noticed. In one case which I observed during several paroxysms, the pain in the region of the stomach was so severe, the vomiting so persistent and ejaculatory, and the subsequent collapse so complete, that the presence of gall stones was suspected. Another case under treatment for several months had at one time an explosive bilious attack; at the next period—four weeks—a typical attack of migraine, in which the stomach symptoms were comparatively obscured. After the paroxysms—be they of bilious or migrainous nature—the patient becomes dull, at times stuporous, the conversation shows confusion of ideas, and the general condition is strongly suggestive of narcotism. The attacks generally last from one to three days. The urine during the attack is very scanty, of high color and specific gravity, and contains an excess of urates. One case during the paroxysm resembled identically the clinical picture of typical uræmia; but the daily examination of the urine, of both morning and evening voiding, and of the total daily quantity excluded nephritis, either with or without albuminuria. In another curious case, the subject of lithæmic paroxysms could always predict the exact day of a bilious attack by the appearance of herpes preputialis and a mild non-specific urethritis.

Migraine.—Many if not most of the cases of migraine are lithæmic in their origin. A history of irregular gout or rheumatism which is hereditary can often be elicited. Lithæmic migraine differs in no particular from that due to other causes. Premonitory symptoms, generally of the special senses, are common. The headache begins as a burning spot about the cheek, eye, or temple, from which it spreads until the whole side of the face and head is involved. Redness of the affected side, particularly of the upper part of the face and ear, can be noticed. Nausea and vomiting are commonly present, but the attack may be strictly confined to the head. Numbness of the affected side, associated with a sensation of tingling, the writer has noticed in most cases. The attacks may last from a few hours to several days, and may be precipitated by gross errors in diet. Narcotism following immediately upon an attack of migraine is not uncommon, although not so frequent as after bilious paroxysms. The association of migraine with attacks of biliousness, and their alternation one with the other, have already been commented upon. The work of Rachford upon the urine of patients suffering from migraine is particularly interesting. After paroxysms of this nature he has been able to separate two of the xanthin bases in considerable quantity from the urine, and by injecting these substances into the lower animals has induced attacks very similar to migraine in human beings.

Headaches.—Besides the headache which accompanies migraine or other lithæmic paroxysms, the writer has noticed two forms of headache occurring in persons of lithæmic habit. Among a large number of patients, headaches are so very common and so often secondary in origin that all reflex causes must be excluded. The facilities afforded by the various clinics in dispensary work—the eye, the ear, throat, and nose, and the gynæcological—enable the clinician to have a thorough examination made in every case of obstinate headache or in any in which there is the slightest reason to suppose the trouble is reflex.

Particular care, too, has been taken to exclude the headaches—so common among the poorer classes in dispensary practice—that are due to bad hygiene, poor food, long hours of work, shortened rest, various excesses, etc. A change in the habits of life and tonics are specific in these cases.

The first class of headaches occurring in lithæmics, most commonly in women about thirty-five or forty years of age, is that in which no reflex cause—particularly uterine—can be detected. These are of long standing, more or less constantly present, and subject to periodic exacerbations. The pain is most commonly occipital, quite severe in character, and sometimes extends to the neck. These patients are not neurasthenics, and organic heart disease is not present. There are evidences of increased vascular tension, viz., a somewhat rigid artery, full between the beats, and an accentuated second aortic sound; but chemicals, the centrifuge, and the microscope fail to reveal other evidences of kidney disease. These headaches are not, in the writer's opinion, those of

general arterio-sclerosis. The exacerbations are neuralgic in character, but not severe enough to constitute a regular attack of neuralgia. Regulation of all the functions of the body fails to relieve these cases, and the drugs commonly used for headache have little or no effect.

Another class of lithæmic headaches occurs in young adults. The headache is notably worse in the morning, is not particularly severe, and is not generally attended with exacerbations. The pain is located in the frontal or the temporal region, or in both regions. Acne is very often present. As etiological factors, anæmia, organic heart or kidney disease, neurasthenia, and chronic constipation can be excluded. Here, as in the first-mentioned class, the arterial tension is raised. Antilithic treatment is the only method which will effectually cure these headaches.

Arthritic and Muscular Symptoms.—The symptoms referable to these systems are probably not due to the same etiologic agents which induce migraine and other lithæmic paroxysms, but certain other products of faulty nitrogen metabolism—possibly excess of uric acid—are probably the causative agents. These cases are commonly diagnosticated subacute or chronic rheumatism and myalgia. Antirheumatic remedies are of value only as analgesics, but a non-nitrogenous diet and general eliminative treatment are followed by permanent freedom from symptoms.

These patients have more or less constant pains in the back and legs, with an occasional outbreak of pain in one or more joints. Very often they complain of a general pain and soreness in the back and limbs, resembling that from a severe beating. The association of symptoms indicative of chronic indigestion with arthritic and muscular pains is very constant. The patient immediately volunteers the information that he has suffered for years from chronic rheumatism and dyspepsia, and the fact that the dyspeptic symptoms disappear during an outbreak of pain in the joint is easily elicited.

Other symptoms of a nervous character which are commonly observed in all lithæmics are irritability, instability of temper, mental depression, and insomnia. Careful attention to family history shows that heredity plays an important rôle.

Treatment.—The treatment of lithæmia is generally very satisfactory, both in avoiding the distressing paroxysms and in securing freedom from the symptoms more or less constantly present. The two cardinal rules which sum up the whole subject are: eliminate the toxic agents which cause the symptoms and avoid nitrogenous food, from the metabolism of which the toxic agents result. It is often a matter of considerable difficulty to feed lithæmics properly, because generally a complete change in diet is necessary, and the monotony of non-nitrogenous food is very unpleasant.

Milk, vegetables, and cereals are the best food for lithæmics, and all cases marked by pronounced symptoms should be kept strictly to the above articles. However, in the management of most cases it is necessary only to direct the patient to eat sparingly and of simple food, and to caution particularly against overindulgence in food of any kind. Stress should be laid upon the latter, because it is certain that overeating constitutes the cause of many cases of lithæmia. To proscribe proteids entirely means to eliminate from the dietary most of the ordinary articles of food, and this is practically impossible. Indeed, some nitrogen in the food is necessary to replace the waste occasioned by metabolism. Meat, fish, poultry, eggs, tea, and coffee should occupy an inconspicuous place in the dietary; while carbohydrates, fats, and milk should make up the list from which the patient can choose. Vegetables in general and fruits are well borne; so also are cereals and small quantities of cheese. It is not necessary to eschew meat entirely; it may be allowed in small quantities at the midday meal, if special injunctions are given that moderation must be observed. The meat may be stewed, as recommended by Kolisch, by which process it is deprived of most of the extractives. If desirable, boiled fish or poultry in small quantities may be substituted for the meat. It is observed that occasionally certain vegetables and fruits disagree with the patient, in which case the offending article must be avoided. Other foods to be interdicted are salads of all kinds, fries, sweet articles—such as preserves, candies, pastries—and malt liquors. Spirits, as a general rule, are injurious, but the writer has observed that their moderate use in some cases is not disadvantageous.

Not infrequently the sudden change in the chemical composition of the diet will, as Haig pointed out, cause an increase in the severity of the symptoms. This condition, however, is explained on physiological grounds, and, because evanescent, should be ignored. During this period of exaggeration of symptoms, it is well to insist upon freedom from the cares of business and a few days rest in bed.

The fact that the causative toxic agents are eliminated by the kidneys, bowels, and skin gives the clew to the medicinal treatment of lithæmia. These emunctories should all be gently stimulated by non-irritating agents. The treatment is best begun either by a brisk mercurial purge or with small doses of calomel and soda, given until free catharsis is produced. If constipation be a marked feature, this must be overcome by carefully adapted doses of cascara, given preferably in glycerin once or twice a day as the case requires.

The drugs which, in the writer's experience, produce the best results as general eliminants are the phosphate of sodium and the bitartrate of lithium. The salts of lithium have for a long time enjoyed the reputation of being of especial value in the treatment of lithæmia. A series of experiments conducted by myself to determine the relative values of the citrate, carbonate, and bitartrate of lithium in these cases was conclusive as to the vast superiority of the last-mentioned salt. Not only is it a better diuretic, but it seems to have a specific eliminative power on the alloxuric bodies which are probably the cause of the lithæmic manifestations. Furthermore, its prolonged use is unattended by any disturbances whatever.

While it is necessary to secure satisfactory bowel movements, it is equally important to avoid drastic purgation, as this interferes with free diuresis. In most cases the phosphate of sodium has the desired laxative effect; moreover, its cholagogue action in these cases is particularly valuable. The best routine treatment for most cases of lithæmia consists of the administration of the phosphate of sodium in drachm doses once a day, taken preferably in a glass of hot water before breakfast, and from five to ten grains of bitartrate of lithium taken in a glass of water three times a day. These quantities must, of course, be varied to suit individual cases. One drachm of phosphate of sodium may sometimes be repeated to advantage in the course of a day, but the quantity of the lithium salt must be determined by the amount of diuresis produced. One, one and one-half, or two of the effervescing lithia tablets, three times daily in a glass of water, will be found to meet the requirements of nearly all cases. In accordance with Klemperer's observations, that drugs calculated to eliminate toxic agents resulting from faulty nitrogen metabolism are given to best advantage about four hours after a meal, the writer has followed that rule in the administration of the bitartrate of lithium, and has obtained the happiest results.

In nervous dyspepsia, chronic gastric catarrh, myal-

gia, and very often in migraine, the prognosis is favorable; but in those cases in which the clinical pictures are almost identical with these affections, but in which a lithæmic condition is present, antilithic treatment is the only method attended with good results. There can be little doubt as to the accuracy of this statement; its truth the writer has many times demonstrated to the satisfaction of himself and others.

The value of the salicylates in the treatment of lithæmia is, in the writer's opinion, decidedly negative. Their powers of elimination have been greatly overestimated. It is true that their ingestion is followed by increased excretion of uric acid, but this is due to an increased production of this constituent. It is well known that the salicylates increase leucocytosis; and, as Horbaczewski demonstrated, much of the uric acid excreted comes from the catabolism of the nuclein of the leucocytes. It is, therefore, manifestly improper to administer a remedy which causes increased production of any of the alloxuric bodies. Just at this point the writer would like to express an opinion, based upon several years of clinical observations, concerning the therapeutic value of the salicylates in those affections for which they are commonly given. In acute rheumatism they are of decided value as analgesics; but in many cases of chronic rheumatism, and in all cases of lithæmia and gout, they are of doubtful therapeutic effect.

The excretory activity of the skin is best maintained by frequent bathing. Hot-water baths, taken either every day or on alternate days, are of positive value in the treatment of lithæmia. The reputation of the many lithia waters is probably due more to the water they contain than to any of the salts; at any rate they are not to be relied upon, exclusive of other medication. Good pure water, taken frequently during the day in liberal quantities, is to be commended.

The general treatment above detailed—viz., the use of a non-nitrogenous diet and frequent bathing, the administration of phosphate of sodium and bitartrate of lithium, given preferably in the form of effervescent lithia tablets—will generally suffice to rid lithæmics of not only the distressing bilious and migrainous paroxysms, but also of the symptoms referable to the gastro-intestinal tract.

The two classes of headaches mentioned above have yielded to this treatment when cannabis indica, the iodides, salicylates, methyl blue, and the host of other remedies ordinarily used for obstinate headaches have failed. It is often necessary to treat individual symptoms when pronounced enough to occasion distress. In those cases in which the symptoms of acid dyspepsia are more or less constantly present, which symptoms occasionally culminate in an attack of biliousness or "sick headache," the remedy popularized by Dr. J. P. Crozer Griffith has given excellent results. It is an alkaline aromatic, the formula of which is:

℞ Ol. caryophylli ..... ʒ i.
Sodii bicarb ..... ʒ ij.
Chloroformi ..... gtt. cxx.
Tr. cardamomi comp. ..... q.s. ad ʒ iij.
M. S. Teaspoonful to be taken after each meal.

The writer has found the efficacy of the above mixture increased by the addition of the oil of cajuput in doses of from five to ten minims. In this class of cases, particularly those in which there are present much flatulence and other symptoms of intestinal indigestion, associated with headaches, a compound tablet of bismuth beta-naphthol, containing bismuth beta-naphthol, 3 gr.; eucalyptol, ¼ gr.; guaiacol, ¼ gr.; thymol, ⅛ gr., given three times daily, is of value. The best results are obtained in the general treatment of lithæmia by adopting a brisk eliminative measure during the first two weeks, then reducing the quantities of the drugs for the second fortnight, then again reducing to a minimum, or intermitting them entirely for the fifth and sixth weeks. In many cases small doses of phosphate of sodium and bitartrate of lithium, given continuously, will keep the symptoms in abeyance.

THE METHOD OF OPERATING FOR SMALL EPITHELIOMATA OF THE LIP.[1]

By CHARLES N. DOWD, M.D.,
ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL.

Cancers which come on the lip are situated in a most favorable position for cure. They are seen soon after their inception. The tissues can easily be removed about them, and the lymphatics through which they spread are so situated that enlargement can readily be noticed and their removal quickly accomplished. Yet

Fig. 1.—Case I., Two Months after Operation.

in spite of these favorable conditions the mortality from these growths is large. The report of 305 cases from Bruns'[2] clinic gives the following details: 28 cases were inoperable or declined operation for other reasons. Of the 277 patients who had been operated upon, 99, or 35.7 per cent., died of recurrence; 16, or 5.7 per cent., died from the operation; 71, or 25.6 per cent., died from other diseases without recurrence; 89, or 32.1 per cent., were living and healthy; 2, or 0.7 per cent., were living with recurrences. Two hundred and twenty-seven of the cases were operated upon three years or more before the report, and 106, or 46.2 per cent., had lived three or more years without recurrence.

Of 62 cases reported by Winiwarter,[3] 4 were in-

[1] Read before the Medical Society of the County of New York, December 27, 1897.

operable. Of the 58 operable patients, 14, or 24.1 per cent., died of recurrence; 2, or 3.5 per cent., died from the operation; 4, or 6.9 per cent., died from other disease without recurrence; 29, or 50.7 per cent., were living at the time of the report without recurrence; 3, or 5.2 per cent., were living with recurrence or were untraced; 6, or 10.3 per cent., were healed. Their history after they left the hospital was unknown.

FIG. 2.—Incisions for Operation in Case I.

Of the 48 patients whose operations had preceded the report by three or more years, 21, or 43.7 per cent., had lived three years or more without recurrence.

These tables certainly indicate the gravity of the disease, but as the earlier cases of the series date back many years they do not fairly show the present status of the subject, since patients now seek surgical aid at an earlier date than formerly and operation is much more successful.

The advanced stage which the growths had reached at the time of operation is indicated by the fact that out of 290 patients in whom the location of the growth is recorded 66 had all, or nearly all, the lower lip involved.

The disease is not uncommon. Wörner, from the statistics of several European clinics, found that 32.4 per cent. of all the epitheliomata which came to operation were upon the lip. They constituted 54.5 per cent. of all those upon the face and scalp. At the New York Cancer Hospital during the last five years patients with cancer of the lip have been admitted at the rate of about one a month.

Each year patients are seen there who have been previously operated upon but who have recurrences in the tissues beneath the lower jaw. In the hope of helping to prevent such recurrences I venture to call the attention of the society to certain elements in the treatment of these growths when they first appear. The patients usually consult a physician before the growth has reached a large size. Frequently it is not larger than a split bean when it comes under medical care. The persistent ulceration is the most important element in the diagnosis, although a hard base is usually present and at least a part of the margin is usually excavated. The ordinary method of treatment is by excision of a wedge-shaped piece of the lower lip and sewing the edges of the wound together—an operation which is easily done, which gives a good cosmetic effect, and which in the main is successful. It is very generally done by physicians who do not undertake the severer kinds of operations. The later history of such patients is not usually followed. They will not report to their surgeon or physician, as they consider their ailment a slight one and they are usually lost sight of. Still a sufficient number of them are afterward seen with recurrences to indicate that the operation is not all that could be wished.

Gussenbauer[1] has made an exhaustive study of lymphatic infection in cancer of the lip, and has found that it almost always exists. Among thirty-two ordinary cases which came to him for operation, from six months to two years after the beginning of the growth, he found lymphatic cancerous disease present in twenty-nine, and in the remaining three there were such changes as indicated a beginning infection. He found the lymph nodes which lie in front of the facial artery close to the upper border of the submaxillary salivary gland to be the ones most frequently infected. He advocated their removal.

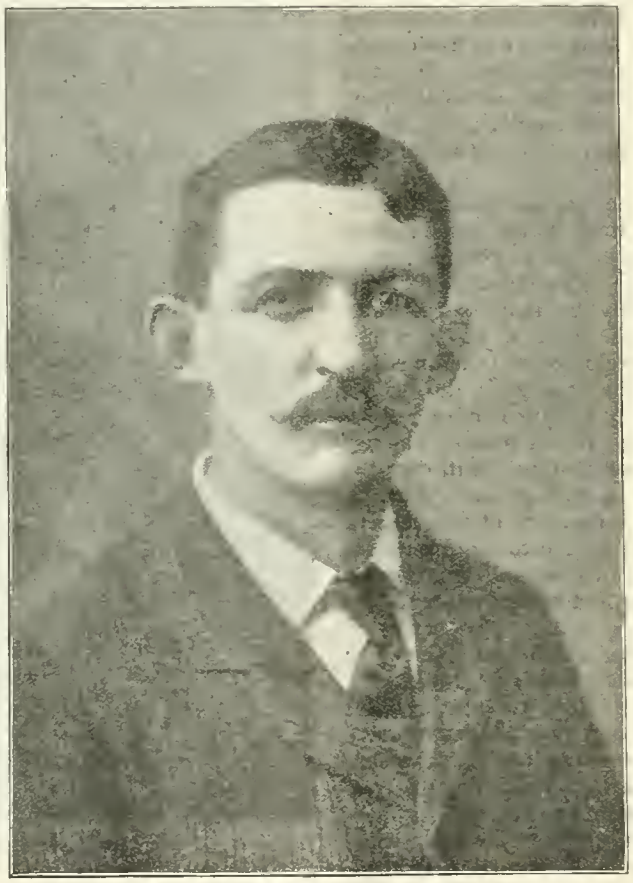

FIG. 3.—Case II., Two Months after Operation.

Wörner also advocated the exploration of the submaxillary tissues in operations for cancer of the lip, whether enlarged lymph nodes could be felt or not, and stated that he had often found them present when they could not be felt before exploration was made. Among 123 patients in whom the clinical appearance was noted the submaxillary glands alone were enlarged in 34; the submental glands alone were enlarged in 30; both submaxillary and submental glands were enlarged in 27; no enlargement was detected in 32.

Winiwarter states that the ordinary course of lymphatic involvement is, first, the submaxillary group, then the submental group, then those on both sides of the neck down to the clavicle.

It is to this submaxillary group that I wish particularly to call your attention. These glands bear a relationship to beginning epithelioma of the lower lip very similar to that of the axillary group to cancer of the breast. Enlargement is usually first noticed in one or more lymph nodes which lie contiguous to the anterior border of the submaxillary salivary gland, and which can ordinarily be palpated if one

FIG. 4.—Incisions for Operation in Case II.

[1] Gussenbauer: Zeitschrift für Heilkunde, 1881, Bd. ii., S. 17.

finger is put in the floor of the mouth under the lower margin of the body of the jaw, just in front of the facial artery, and counter-pressure made with the fingers of the other hand on the outside. A very small amount of swelling can thus be discovered. During the past year it has been my fortune to operate upon four cases of small epithelioma of the lower lip, which had been examined by men who were careful in diagnosis, but who had stated that there were no lymphatic enlargements. Yet when examination was made in the manner indicated, enlarged lymph nodes were detected in each case.

The fact that these glands are enlarged does not necessarily mean that they are cancerous. Instances are recorded in which palpable lymph nodes have been left after removal of a portion of the lip, and in which the swelling has subsided. In those of my case, specimens from which were examined microscopically, no cancer cells were found; the lymph nodes from the fourth case were lost before reaching the pathologist. Still one must feel that enlarged lymph nodes near a cancer are a great menace and that they should be removed. Gussenbauer's researches and the recurrences which are seen from time to time strengthen this belief to the extent that a failure to remove them seems very culpable.

The method which seems best adapted for these cases is to make an incision under the body of the

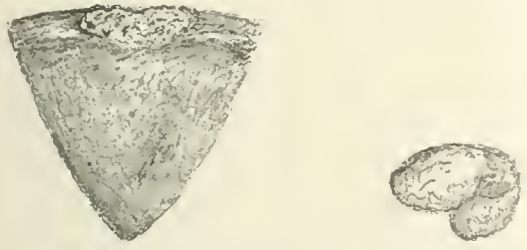

FIG. 5.—Case III., Showing signs of visible epithelioma, the portion of lip removed, and the submaxillary lymph nodes.

jaw, about an inch in length, reaching forward from the position of the facial artery; this is carried through the skin, superficial fascia, platysma, and deep fascia, down to the submaxillary salivary gland, to the anterior border of which the lymph node or nodes are attached. The posterior border of the mylo-hyoid muscle may be pulled forward to facilitate their finding and removal. Through the incision the adjoining tissues can be examined for the purpose of detecting other enlarged lymph nodes, particularly along the facial artery and in the floor of the mouth. If such are detected they should be removed, and of course the incision should be made as large as necessary. Incisions which are not more than an inch in length on each side do not make a scar which can be considered a deformity; if situated just below the border of the jaw, they are hardly seen. This procedure should not lengthen the time of healing from the operation, as the submaxillary regions should heal as quickly as the lip does.

The chief objection is the fact that an anæsthetic has to be given—a very slight objection when compared with the benefits of the operation—so slight that it need not be considered.

There may be some exceptional instances when these incisions need not be made, as there are some persons with thin necks in whom enlarged lymph nodes can be detected by proper palpation, if they exist. But so thorough and careful a bimanual examination should be made in each case that slight enlargements can be detected, and if they exist, or if there is any doubt about it, the exploration should be made. On this basis there will be very few patients with even small epithelioma of the lower lip in whom the submaxillary spaces will not be explored. The recurrent cases and the records of operations indicate that this is not often enough done, although the subject has been fairly before the profession for a number of years.

The removal of the growth itself from the lip should be accomplished by taking away a good-sized wedge of tissue. The cut should be one-fourth to one-half an inch from the visible edge of the epithelioma. A large portion of the lip can be removed without making an unsightly deformity.

The accompanying illustrations indicate the good cosmetic results which are obtained even when large portions of the lip are removed. If more than two-thirds of the lip is taken away, it is usually wise to make a small incision outward from the angle of the mouth, cutting the mucous membrane one-half or one-third of an inch higher than the skin, sewing this over to the skin margin so as to form a good vermilion border, which will be a part of the newly constructed lip, and then sliding the flap toward the median line. A compensatory V-shaped piece may be taken from the tissue above the incision, if necessary.

Clinical Department.

REPORT OF A CASE OF SUBCUTANEOUS FACIAL HEMORRHAGE IN EPILEPSY, WHICH FOLLOWED A SINGLE FIT.

By L. PIERCE CLARK, M.D.,

FIRST ASSISTANT PHYSICIAN AT CRAIG COLONY, SONYEA, N. Y.; MEMBER OF THE NEW YORK NEUROLOGICAL SOCIETY, ETC.

MANY writers upon epilepsy have mentioned the occurrence of subcutaneous hemorrhage throughout all the organs of the body, and especially in the condition status epilepticus, but few of these writers have made any more extended remarks than simply to note its occurrence. Gowers ("Diseases of the Nervous System," vol. ii., p. 744) states that the strain of a seizure in epilepsy may cause small vessels to rupture, usually in the face and conjunctivæ, so that the face may be spattered, as it were, with small hemorrrhagic points. After death in a convulsion hemorrhage may be found in the internal organs. No further remarks are made by this writer in regard to the frequency or infrequency of subcutaneous hemorrhages in epilepsy. It is not an uncommon observation to see this hemorrhagic condition in epilepsy when the patient has had status epilepticus or many seizures occurring in series. The writer can find no case on record in which hemorrhages have followed a single grand-mal seizure or petit-mal attack. In the case which is to be here reported the patient has for two or three years had subcutaneous facial hemorrhages after having had a single attack. The history of the case is as follows:

C. F——, female, aged seventeen. Epilepsy began at the age of eleven, supposed to have been caused by shock on hearing of a sister's death. The family's history is as follows: Paternal grandfather died of phthisis; maternal grandfather and grandmother both died of hemorrhages of the brain at the age of sixty-five; a maternal aunt died of apoplexy at the age of thirty-seven; an elder sister had chorea and died of phthisis at the age of thirteen; a younger sister is at present suffering from phthisis; all the brothers and sisters have had night terrors and disordered sleep in childhood—in fact, these have always been present in all the patient's paternal relatives. The patient's mother has had hysteria and hysterical convulsions on several occasions for eight or ten years prior to the birth of the patient; one hysterical attack occurred when the mother was two months pregnant; another attack occurred while the patient was being born. Nothing pointing to a hemorrhagic diathesis was found in the

family history. The patient had scarlet fever at seven years of age, and scarlatinal nephritis followed. She has had frequent attacks of headache from earliest infancy, which have been termed by the relatives "ner-

vous headaches;" such attacks have occurred most frequently in the early morning hours. The patient has never been regarded as a healthy child, and received the greater part of her education in private schools. She has a very large appetite and is prone to bolt her food and to eat large and inordinate quantities of food several times a day. On several occasions after having had a large number of epileptic seizures the patient has lost the power of both hands, so that she could not pick up small articles from the floor or hold them when once grasped. This condition lasted only a few hours after her attacks, which occurred in series. (This is an illustration of the post-paroxysmal paralysis in epilepsy described by Hughlings-Jackson.) She has never had a sleep stage after her attacks. She has never done much work. Since her epilepsy began she has suffered from considerable impairment of memory. A few light attacks have been aborted by shaking and rubbing the patient's arms. She presents marked stigmata of degeneration, which are as follows: palate Gothic: torus asymmetrical: ears asymmetrical.

The patient was admitted to Craig Colony for care and treatment, March, 1897. Three days after admission she had a slight seizure which was attended by a slight muscular convulsion. After this attack a profuse rash or a subcutaneous hemorrhage appeared on the face and extended down the neck on the right side. This rash remained for two days, and then finally faded out in the characteristic manner in which recovery from purpura hæmorrhagica takes place. This hemorrhagic condition is shown in the illustration presented here, which is from a photograph taken one day after the hemorrhage occurred. In the first few hours the hemorrhagic foci resemble India-ink tattoo marks, or, as the huntsman would term it, "powder marks."

A description of one of her attacks which was witnessed by the writer is as follows: Patient gave the characteristic epileptic cry; a convulsive movement began in the feet, followed immediately by severe muscular contraction throughout the entire body. Patient had labored breathing and frothed at the mouth. After this convulsive movement had ceased, at the end of twenty seconds, the patient succeeded in standing up and gave two short screams; then she lay down on the bed again and fell into a stupor which lasted about ten minutes. During the clonic stage of the spasm a fine eruption rapidly appeared on the face and neck.

After several of her epileptic seizures had occurred and the hemorrhage had made its appearance after each attack, she was placed upon three minims of the fluid extract of ergot twice a day. This resulted in marked diminution of the quantity and area of the hemorrhage on the face and neck. When she had taken the ergot for two weeks the facial hemorrhages ceased to appear after the convulsions, and she has had none since.

HEMILINGUAL ATROPHY WITH COEXISTING BULBAR SYMPTOMS, ASSOCIATED WITH INSANITY OTHER THAN GENERAL PARALYSIS.

By WARREN L. BABCOCK, M.D.,
ASSISTANT PHYSICIAN, ST. LAWRENCE STATE HOSPITAL.

This rare symptom of nuclear disease has always received considerable attention from neurologists. Somewhat over a year ago C. W. Burr[1] contributed an elaborate review of the subject and reported an additional case. The last twelve months have brought forth several new cases. Under the head of "Trophoneuroses" in the "Twentieth Century Practice," Charles K. Mills writes interestingly and gives all known information regarding its etiology and pathology. He corroborates the conclusion of Burr that "hemiatrophy of the tongue with palsy can be caused only by a lesion of the hypoglossal nerve or its nucleus in the medulla." The greater part of the evidence adduced shows that in the majority of cases it is due to nuclear disease of the hypoglossal, although the lesion seldom involves the twelfth nucleus alone. More often the accompanying paralysis of palatal, laryngeal, and other groups of muscles: the frequent association with tabes, paresis, and the myelitic degenerations; and the sensory implications, show that it may be simply a symptom of an extensive nuclear degeneration. The case reported below is one of some interest, owing to the accompanying bulbar symptoms and associated mental condition. After a careful review of the literature, the reporter is unaware that a case associated with insanity other than general paralysis has heretofore been reported.

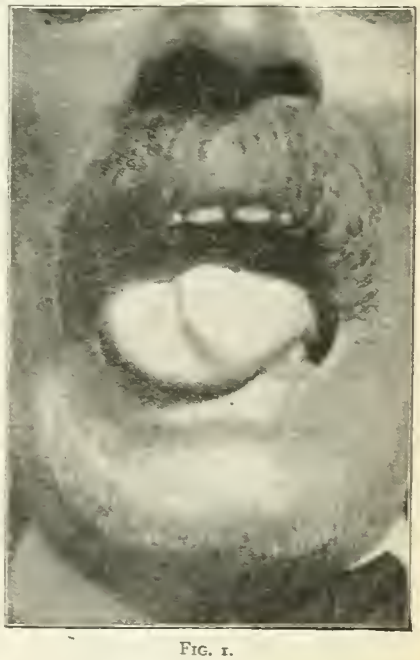

Fig. 1.

[1] Journal of Nervous and Mental Disease, 1896, p. 2[illegible]

Case No. 2,727.—Admitted to St. Lawrence State Hospital, April 1, 1897; male, aged fifty-seven years, married, native American; laborer and a veteran of the rebellion. Occasional drinker, but seldom given to excesses. No history of syphilis. Father intemperate, but family history otherwise good. Diagnosis, melancholia with hypochondria, beginning three months previous to admission. Patient's wife states that he suffered a "congestive attack" in December, 1895. He regained consciousness in a few minutes, and soon observed partial loss of muscular power on the left side of the body, with almost complete loss of sensibility of the right side of the face, left arm, and left thigh and leg. The physician who was called in found greatly contracted pupils, tongue protruding to right, speech somewhat thick and guttural, and loss of muscular power and sensibility of the left side of the body. Later the patient regained partial use of the left arm and leg; he had some difficulty in swallowing, which soon passed off, and he became able to articulate distinctly. Still later all symptoms disappeared except the pupillary contraction, deviation of the tongue to the right, and some slight difficulty in deglutition. The condition remained stationary for four months, when he began again to lose use of the left arm and leg, swallowing became more difficult, speech thick and jerky, and he suffered severely from headaches limited to the right side of the head. Following the return of his symptoms he became depressed, threatened suicide, and had emotional outbreaks followed by periods of great irritability. In this condition he was admitted to the hospital.

Examination, physical: Temperature normal; pulse, 118, soft and regular. Heart moderately hypertrophied, with roughened second sound. Lungs normal. Bowels constipated, prostate hypertrophied, and bladder irritable. Urine: Specific gravity, 1.013; trace of albumin with many coarse granular casts; urea, one per cent. Eyes: Convergent squint, right eye; pupil contracted nearly to a pin point; visual field normal in left eye; inferior, superior, and temporal field blind to right eye; fair central vision; iridoplegia present; no diplopia; ophthalmoscope gave shrunken arteries, dilated and tortuous veins, and sluggish circulation. Tongue: Heavily coated white, moist, deviating to right; right hemisegment greatly atrophied (see Fig. 1); antero-posterior median line prominent; marked fibrillary twitching on protrusion. Palatal and laryngeal muscles of right side of pharynx and throat paralyzed and atrophied, rendering deglutition difficult; fluids only could be swallowed, part of the same usually flowing back into the nares and out of the nostrils. Uvula deviated to right. Mucous membrane of mouth smooth and without folds; semisolids had a tendency to collect in right cheek; he constantly drooled saliva at night; taste and smell normal; speech thick and guttural and attended by considerable effort in articulation. Labials only could be pronounced with ease. Patellar reflexes normal; no ankle clonus; superficial reflexes of right side absent; no inco-ordination of arms or legs. Sensibility completely lost over the right side of the face, partially lost over the left arm and shoulder. Trophic ulcers on right side of face and in right nostril. Cephalagia at times intense and usually located over right side.

Examination, psychical: Depressed and despondent; threatened both suicide and homicide; notional, demanding that his wife or nurse wait on him constantly; wished food served eight or ten times daily, and changed physician six times in two months. Often irritable, and if crossed in any way would scold and threaten, break furniture, or beat his wife. Thought family desired to have him out of the way. Exceedingly introspective and hypochondriacal, spending the greater part of the day in self-analysis or review of subjective symptoms. Wept frequently and without apparent cause. Loss of memory for recent events, with slowly progressing dementia.

Progress of Medical Science.

A Clinical Study of Tachycardia and its Relation to Uræmia and Graves' Disease.—R. G. Curtin (*International Medical Magazine*, 1897) says that in certain cases of so-called "nervous" palpitation, the underlying cause is an uræmic intoxication. In other cases the tachycardia is the first symptom of Basedow's disease, and precedes by many years the other symptoms. Of fifty-five cases of Basedow's, thirty-four came under this heading.

Streptococcus Erysipelatos and Streptococcus Pyogenes.—Contrary to Koch, Petruschky, and others, C. Parascandolo (*Wiener klinische Wochenschrift*, 1897, Nos. 38 and 39) is of the opinion that there is a difference between the above streptococci. In favor of his view he advances the argument that the serum of an animal which has been rendered immune with the streptococcus of erysipelas does not protect against infection with streptococcus pyogenes.

Varicosities.—They result in part from a general slowing of the pelvic circulation, with consequent engorgement of all the pelvic viscera and the damming back of the blood in the enlarged veins, and in part from direct pressure of the pregnant uterus upon the engorged pelvic vessels. Generally the varicose condition is first manifested in the appearance of hemorrhoids, from which many patients suffer severely. If the condition becomes aggravated, the veins of the vulva and of the legs distend, often to an enormous extent. We have seen in a Hungarian woman a mass of varicose veins as large as a man's fist, pendent from the right labium. A curious feature noticed by some writers is that varicose veins of the legs are commonest upon the left side, and when present upon both limbs are more marked upon that side (H. C. Bloom). This is by no means invariably the case. The veins of the bladder may partake in the general distention, and should rupture of one of these veins occur hæmaturia will be produced.—W. A. Newman Dorlan, "Manual of Obstetrics," page 86.

On the Etiology and Therapy of Uncontrollable Vomiting in Pregnancy; Treatment with Subcutaneous Injections of Cocaine, Tibone's Method.—A. Pozzi (*Therapeutische Wochenschrift*, No. 37, 1897), in an exhaustive *résumé* of the literature of the past one hundred and fifty years, introduces his subject by quoting Charpentier, who says that the large number of remedies recommended by various writers from time to time is in itself sufficient proof of their uncertain value. He states that Oribasius and Paulus were the first to observe that the vomiting of pregnancy could prove uncontrollable. In 1641 Guillemeau differentiated a form of vomiting characterized by its severity and long duration, and requiring energetic treatment. Mauriceau (1738) claimed that obstinate vomiting was a purely functional disorder and required suggestive therapy. He believed that a direct connection existed between the sympathetic nerves of the stomach and those of the uterus, so that dilatation of the uterus caused reflex nausea and vomiting. His treatment was dietetic and purgative, and in severe cases dry cupping in the epigastric region or the wearing of a vulture skin. His theory remained in general

acceptance up to the middle of the present century. Some writers locate the seat of trouble in the uterus, others in the cervix, and still others in the adnexa. Bretonneau (1854) believed that the reflex vomiting resulted from the stretching of the rigid uterine wall and recommended the use of belladonna. Horwitz thought that extensive metritis and parametritis caused vomiting by interfering with dilatation, and that deviations of the uterus and inflammation of the cervix increased this difficulty. Giordano considered as a causative factor the irritation of the ovaries produced by contact with the fundus uteri, and regarded induced abortion as the only proper treatment in severe cases. Tyler-Smith and Schröder claimed that stretching of the uterine nerves causes the vomiting; Galabin, that it is due to the tension of the swollen ovary. Cazeaux regarded flexion of the fundus on the cervix as the causative agent; Clay, hyperæsthesia of the cervical mucosa. The patient was therefore kept on her back with the hips elevated, and leeches were applied. Bennet recommended the application of nitrate of silver in inflammation, erosion, or ulceration of the cervix. Copeman advised forced dilatation of the cervix, and this was concurred in by Marcow, Sims, Calebrini, and others. The good results of this method strengthen the theory that the cervix is the seat of irritation. More recently La Torre recommends the application of ichthyol-glycerolate tampons to the cervix, and believes venous congestion of the cervix to be the causative factor. Among the authors who regard uterus deviation as the etiological basis are Guéniot, René Birau, Moreaux, Cazeaux, Munro, and Ulrich. The chief advocate is Graily-Hewitt (1871), who believes deviation to be the sole factor in uncontrollable vomiting. At the point of flexure there arises an irritation of the nerves of the uterus which calls forth reflex vomiting, varying in intensity with the degree of flexion. Correction of the deflection is the only method for procuring relief. Braxton-Hicks claims that in addition to the above adhesions must be present to call forth obstinate vomiting. Various other causes are mentioned, such as enlarged placenta (Taggard); a peculiar form of dyspepsia, due to the unusual food often used (Levai); constipation (Donzellini); and increased nervous excitability causing predisposition, with constipation as the exciting cause (Fischel). One of the latest advanced theories is that of Kaltenbach, who places obstinate vomiting in a category with hysteria. Vomiting and salivation, according to him, are simply the manifestations of an increased reflex neurosis caused and maintained by pregnancy. He admits that the relation to hysteria is not a constant one. Friedreich regards hyperemesis gravidarum as a reflex neurosis, best treated by large doses of potassium iodide. These are the main etiological theories and the treatment dependent upon them. Counter-irritation, vesicant plasters on the epigastrium, emetics and laxatives, aromatics, alkalies, and antispasmodics have all been recommended. As a sedative opium, given internally, in clyster or hypodermatically, does well in certain cases. Sometimes belladonna applied to the cervix or cocaine internally is good. Among the empirical agents employed are the salts of copper, potassium cyanide, aqua laurocerasi, tincture of iodine, potassium iodide, potassium bromide, calomel, and nux vomica. Cerium oxalate in doses of from three to five grains gives good results. Lately local application of ether to the epigastrium and spine has been recommended. Gautier observed that the galvanic current has a quieting action. With a weak, descending current of from eight to forty milliampères applied for fifteen or thirty minutes, with the negative pole placed on the navel and the positive pole between the insertion of the sterno-cleido-mastoid muscle, a sedative effect on the sympathetic, vagus, and phrenic nerves is produced. With an ascending current, positive pole in the region of the stomach, vomiting can be again called forth. Lastly, when all other methods fail, it is proper to induce abortion. In the year 1813, Simmons recommended the induction of premature labor at the seventh month, for uncontrollable vomiting. Abortion should be resorted to only after all other methods have failed to control the vomiting, when loss of flesh and strength makes absolute rest imperative, when fainting-spells occur, and when high and constant elevation of temperature exists. The writer next compares the picture of the physiological with the pathological form of the vomiting of pregnancy. Ordinarily the vomiting begins shortly after conception, lasts from one to four months, is easily controlled, or passes away without treatment; it is almost painless, or associated with epigastric pain; it occurs before and after eating; the vomit consists simply of mucus, or is mixed with the food ingested; the patient may lose flesh and strength. On the other hand, gradually or suddenly, it may pass over into the uncontrollable form, which at first is difficult of differentiation. Usually constant nausea and salivation are then present. The ejected material consists of mucus, food, or bile; vomiting may be painless or painful. There are remissions permitting the ingestion of food; later this becomes impossible, and then loss of flesh and physical and mental depression occur. This marks the beginning of the second period, in which all the former symptoms are intensified, and constant vomiting and fever are added. The third period is recognized by the development of cerebral symptoms, the vomiting ceases, there are delirium, hallucinations, neuralgias, and finally coma and death. The author comes to the following conclusions: 1. No constant pathological lesion is demonstrable in hyperemesis gravidarum; pregnancy is the predisposing cause, but in most cases the exciting cause cannot be discovered. In these cases pregnancy must be regarded as being also the chief cause, either on account of some abnormal course—twin gestation, hydramnios—or as occurring in a person of high nervous temperament. 2. In cases in which the exciting cause is discovered we may expect relief by removing this cause, ulcers of cervix, by dilatation and cauterization, correcting malpositions, or finally by resort to Copeman's method. These methods are not always applicable, and are not without danger; abortion or cervical stenosis may occur. 3. Tibone, who believes that vomiting is reflex and due to impulses originating in a nerve of the reproductive tract, being transmitted through the sympathetic nerves to the vomiting-centre in the cord, recommended breaking this circuit by paralyzing the genital nerves by means of hypodermatic injections of a one-per-cent. solution of cocaine in the epigastric region. This method the writer considers the best therapeutic agent for action on the nervous system in controlling the vomiting, since bromides, chloral, etherization of the spine, etc., merely diminish the nervous irritability. He injects before each meal 0.01 to 0.02 cgm. of cocaine, in difficult cases, three times a day. Excellent results are obtained. Giacosi claims that the action of cocaine on the terminal ends of the sensory nerves is similar to that of curare on the motor-nerve endings, and that the action extends peripherally. Reclus says that in mixed nerves cocaine first paralyzes the sensory fibres and then the motor fibres without previous excitation. The anæsthesia extends along the nerve branches in the skin, is most complete by subcutaneous injection, lasts from ten to fifteen minutes, and affects the superficial before the deeper tissues. Paralysis of the sensory nerve prevents reflex irritation. To overcome the vasoconstrictor action of the cocaine nitroglycerin is added to the solution.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 26, 1898.

THE PATHOLOGY OF SHOCK.

MANY contributions have been made to the pathology of shock, but they have all been clinical rather than pathological. It has been only within recent years that the searching analysis of the cell has been able to afford morphological data upon which a rational pathology of shock could be based. Quite recently two noteworthy contributions have appeared which seem worthy of comment.

Lutzenberger ("Contributo all' anatomia patologica del trauma nervoso," *Annali di Neuroglia*, 15, 1897, fasc. 5) studied the changes occurring in the nervous system of guinea-pigs, following slight trauma to the head and the spinal column. He found that the general disorders of nutrition in these cases shows itself above all in the increase in number of the ganglion cells in all regressive phases. In the ganglion cells situated in the general region about the site of trauma grave alterations are described. These consist in general of a sort of polar distribution of the chromatic substance. The rapid dislocation of the cerebro-spinal fluid could cause a laceration of the spinal cord, which would result in an alteration in the disposition of the white and the gray substances simulating a heterotopia. Lutzenberger also found that in the spinal cord, following trauma, sclerotic plaques are found, and especially in places where the effect of the laceration has been most intense. Dilatation of the capillaries and of the veins is also present. In the medulla are found a great many cellular alterations. If the traumatism is followed by cachexia, the alterations of the cells are marked and resemble those produced by grave pathological alteration of the brain, such as, for instance, those changes noted in general paresis.

C. Parascandola ("Recherches histo-pathologiques sur l'état des centres nerveux dans la commotion thoracique et abdominale expérimentales," *Archives de Physiologie Normale et Pathologique*, 30, 1898, page 138) gives a very extended series of observations on guinea-pigs. He stretched the animals out flat by their feet and gave them a sharp blow upon the abdomen with a flat ruler. The animals reacted in various ways to the traumatism, but the greater number of them after a period of temporary quiet became apparently well, but in from thirty-six to forty-eight hours they died with the symptoms of exhaustion or shock. The cerebrum, cerebellum, medulla, and cord were removed and preserved in appropriate fixatives, and studied by the Golgi, Marchi, and Nissl methods.

The alterations found by the Golgi method consisted in a deformity of the cell body advancing to the grade of actual atrophy, node-like swellings on the dendrites, and fragmentation of the same. By the Marchi methods he noted simple marginal degeneration of Lissauer's zone and of the posterior roots proceeding to degeneration of the posterior columns; in some instances Gowers' tract, the crossed pyramidals, and the direct cerebellar tracts were involved, and sometimes there was a total degeneration of the entire cord. As observed by the methods of Nissl, the cytological alterations were various but pronounced. Chromatolysis was present in a large number of cells. In those affected in a mild degree only, the chromatolysis was more peripheral than central: in the severer grades the chromatolysis was complete. In a large number of the cells peculiar abnormalities in the distribution of the chromophilic granules were noted; there were peculiar perinuclear bonnet-shaped masses, or fusiform, or like a crown about a rarefied perinuclear space. Further, changes in the protoplasm were noted, rarefaction going on to vacuolization, to total disappearance of the cytoplasm. Changes in the achromatic reticulum were noted by the author, consisting in a widening of the mesh and a contraction of the protoplasm within the mesh, resembling an atrophy. Changes in the nucleus were also observed. At times there was an unimportant dislocation, but the gravest changes consisted in a vesicular swelling of the nuclear protoplasm, which varied to a notable degree—at times very slight, at times marked. In some sections there were pronounced abnormalities in the coloration of the nucleus.

With a few more contributions of this nature the involved questions of fatigue, shock, traumatic neurasthenia, traumatic hysteria, and allied phenomena will be understood, and more rational hypotheses bearing on treatment can be evolved.

TESTIFYING AGAINST EACH OTHER.

THE charge against a very reputable physician of this city, of causing the death of an infant by an overdose of medicine, is lamentable from many points of view, all of which must seriously affect the particular parties concerned and also the profession at large. At best we are all liable to errors of judgment, and even when such are committed there is a great deal of room for the exercise of that becoming charity which is as much a professional as it is a Christian duty. The readiness with which some medical men are willing to testify against their brethren in cases of this sort is a deplorable evidence of the weakness of professional vanity and the malignity of personal jealousy. What makes the case more than an ordinary one for these comments, is the fact that there was no proof of any relation of cause and effect in the administration of the medicine and the death of the patient.

It is to be sincerely hoped that thus much will be proved in the forthcoming trial, and that the ungracious and misguided expert witnesses for the prosecution will reap the full benefit of their unenviable position in the matter. At present there is no doubt in the mind of every self-respecting member of the profession that the prosecutors pose as exponents of a very dangerous principle reflecting on the honor and standing of scientific medicine before the public. It is hard enough for any medical man to make a reputation and a living, to discharge the varied and weighty responsibilities constantly thrust upon him, to prove his fitness for his patrons, to solve the many difficult problems of diagnosis and treatment which daily beset him, to balance right motives and good reasons against inevitable risks and constant anxiety—without having his work criticised by some presumptuous and eager professional witness against him.

If such proceedings are allowed to go on without a becoming rebuke, it is not difficult to see what will eventually become of the practice of the best of our men. When brother can thus be arrayed against brother, what must be the ultimate fate of the family? In the hands of shystering lawyers such witnesses lend themselves to the most powerful influences for evil against the entire brotherhood of the profession that can possibly be imagined. They become the wilful betrayers of a trust which should be guarded with as much vigilance as that of personal honor, which, aggregated as a whole, makes the profession what it is. Whatever may be the outcome of the trial, the bad taste, poor judgment, and questionable motives of the experts for the prosecution cannot fail to be strikingly manifest. At best it will be interesting to watch the proceedings, and coax ourselves into the delusive hope that the "better-than-thou" men will prove their right to the future respect and esteem of their brethren.

SOCIAL AND PHYSICAL CONDITION OF NEGROES IN CITIES.

The degeneration of the negro race on this continent has of late attracted much attention, and the reason for this unhappy state of things has been explained in various ways. From the testimony of those who have made a study of the subject, it would appear evident that the chief cause of the degeneracy among the colored people is the sudden alteration in their mode of living that took place after the civil war. They were like children who were freed from any control before they had learned to take care of themselves, and in consequence of this ignorance plunged into dissipation and vice, without thought of the after-effects. Atlanta University has just published in pamphlet form a report of an investigation made by colored graduates under the direction of the university, and also of a conference on negro city life, at which only negroes took part in the discussions. *Outlook*, March 5th, commenting on this report, says: "The facts set forth, therefore, are not to be discredited on the ground that the separation of races has prevented knowledge or distorted that which was obtained. The five cities covered in the report are Atlanta, Ga.; Baltimore, Md.; Charleston, S. C.; Memphis, Tenn.; and Richmond, Va. The average death rate of the whites in these cities during the fifteen years ending in 1895 was twenty-one per thousand; the average death rate among the colored was thirty-six per thousand. In other words, the death rate among the negroes was seventy-four per cent. greater than among the whites. The reasons assigned by the negro investigators for the excessive death rate among their race are of especial interest. In the first place, they find that it is not due so largely as has been supposed to the overcrowding of tenements. Only one-tenth of the negro families investigated lived in one-room houses. In the next place, they find that the sanitary condition of the houses is not primarily responsible for the terrible death rate. The first positive cause assigned for the greater mortality among negroes is the excessive numbers of colored women who must daily abandon their children by going out to work to help support their families. Only one colored man in four, it was found, supported his family without assistance. The other reason assigned by the investigators for the greater mortality among their race is the general ignorance and disregard of the laws of health."

THE DISCOVERIES OF JOSEPH JACKSON LISTER.

That Lord Lister's father was a very great man is a fact that does not seem to be generally known. He was almost as eminent in his particular branch of science as is the discoverer of antisepsis, but the fame of the father has been overshadowed by that of the son. Joseph Jackson Lister, although a man of business, found time to make perhaps the most important improvement in the microscope ever effected and to render possible the marvellous researches in bacteriology of modern times. In addition to this, he was also the first to describe the tendency of the red corpuscles of the blood to arrange themselves in rouleaux. Dr. Henry Smith Williams, in the current number of *Harper's Monthly Magazine*, referring to the older Lister, says: "To Joseph Jackson Lister is due the chief credit for directing those final steps that made the compound microscope a practical instrument instead of a scientific toy, combining mathematical knowledge with mechanical ingenuity; and, having the practical aid of the celebrated optician Tulley, he devised formulæ for the combination of lenses of crown glass with others of flint glass, so adjusted that the refractive errors of one were corrected or compensated by the other, with the result of producing lenses of hitherto unequalled powers of definition. . . . Lister had begun his study of the lens in 1824, but it was not until 1830 that he contributed to the Royal Society the famous paper detailing his theories and experiments. Soon after this various continental opticians, who had long been working on similar lines, took the matter up, and their expositions, in particular that of Amici, introduced the improved compound telescope to the attention of microscopists everywhere."

News of the Week.

Obscene Medical Literature.—We read in the *Southern Medical Record* that the editor of an Iowa medical publication has been convicted on the charge of sending obscene literature through the mails, the ground for the charge being the reproduction of some blackboard vulgarity intended by the students of a medical college for the benefit of the "co-eds."

The New York Hospital.—Extensive changes are soon to be made at the New York Hospital. It is intended to raze the old Thorne house on Sixteenth Street, together with adjoining buildings recently acquired, and to erect three new buildings. On the Sixteenth Street front will be the administration offices, with an out-patient department in the basement. There will also be an eight-story building for the accommodation of private patients and the house staff, and next to this will be the residence of the superintendent. Another building will contain the ambulance stables, laundry, and dormitories for the female servants. Alterations are to be made to the old hospital building, which will give increased facilities in the children's ward, the operating-theatre, the apothecary's department, and the reception wards.

Plague Riots in Bombay.—Serious rioting broke out in Bombay on March 8th among the low-caste Hindus and Mohammedans, against the Europeans. It had its origin in an attack upon a plague-search party. Two soldiers were killed, and the police fired on the mob, killing seven persons and wounding many others. The mob attacked one of the plague hospitals, burned the offices and stores, and savagely assaulted the doctors, killing one of the latter. Three soldiers on police duty were stoned to death by the rioters.

Dr. Waldemar v. Schroeder, professor of pharmacology in the University of Heidelberg, died on January 28, 1898, of heart disease, in his forty-eighth year. When in 1890 the chair of pharmacology was added to the university, Dr. v. Schroeder received the appointment, and was also director of the new institute.

Kissing the Bible.—Justice Kudlich has ruled that in his court witnesses need not "kiss the book." In announcing this the other day he said that an instance of transmission of disease, due to the custom, had come under his observation. In this decision the justice proves himself true to hereditary instinct as well as a wise judge, his father being a well-known physician.

Medical Charity Abuse.—At a recent meeting of the Medico-Legal Society, held in Philadelphia, this subject was discussed at some length. It was held that the chief cause of the abuse lay in the medical profession. It was suggested that a hundred physicians should be appointed a commission, which should meet from time to time and discuss things of interest to the profession. It was decided that the co-operation of all general and special practitioners should be enlisted in the work; that medical education should be so modified as to limit the number of specialists; that the government should control its own benevolent institutions and separate these from corporations of medical men who conduct hospitals for their own benefit; and, finally, that appropriations of public money should be made only to charitable medical institutions under the supervision of the commission to be created.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C., March 21, 1898.—Changes in the medical corps of the United States navy for the week ending March 19, 1898. March 10th.—Medical Inspector W. S. Dixon detached from the *Brooklyn* and ordered at once to the hospital, Norfolk, for treatment; Medical Inspector P. Fitzsimons detached from duty as a member of the board of inspection and survey, Washington, D. C., and ordered to the *Brooklyn*. March 17th.—Surgeon J. E. Gardner ordered to the *Dolphin*, March 24th; Passed Assistant Surgeon T. W. Richards detached from the New York navy yard and ordered to the *Machias*, March 22d; Passed Assistant Surgeon M. R. Pigott detached from the *Machias*, March 22d, proceeding home and awaiting orders.

Obituary Notes.—Dr. Thomas J. Moore, of Richmond, Va., died on February 24th, aged fifty-eight years. He was a graduate of the medical department of the University of the City of New York in the class of 1868. He was chairman of the medical department and professor of clinical medicine in the University College of Medicine, and visiting physician to the Virginia Hospital, Richmond.—Dr. J. T. Conkling died at his home in Brooklyn, on March 17th, after a long illness. He was a graduate of the College of Physicians and Surgeons in this city in 1855, and was at one time a health commissioner of Brooklyn. He leaves a son, a physician, and a daughter.—Dr. John B. Brooke, of Reading, Pa., died on March 19th, at the age of sixty-two years. He was graduated from the Jefferson Medical College in 1858.—Dr. Elizabeth S. Dalbey-Norred died in Minneapolis, Minn. She was born in Wells County, Ind., October 14, 1843, and was graduated from the Woman's Medical College of Chicago in the class of 1881. She was a member of the Illinois State Medical Society, the Minnesota Medical Society, and the American Medical Association.

Proffers of Medical Service.—Surgeon-General Van Reypen, of the navy, has received over three hundred offers from physicians of service as acting assistant surgeons in the navy. These offers cannot be accepted until Congress authorizes the temporary appointment of acting surgeons. There are about twenty vacancies in the regular service, for which there are few or no applications because of the humiliating treatment to which newly appointed assistant surgeons are subjected. If Congress will remove these objectionable features and will authorize the appointment of acting assistant surgeons, there will be no lack of competent men for the vacancies.

The Sale of Patent Medicines.—A bill now before the New York State legislature, which was reported out of committee on March 16th, provides that no pa-

tent medicine shall be sold or exposed for sale in this State, unless the formula is printed on the label of the bottle or package containing such medicine, and also on the outside wrapper. The printing of an incorrect formula or the sale of a patent medicine without the formula provided for in the act shall be a misdemeanor, punishable by not less than three months' nor more than one year's imprisonment, or by a fine of not less than $50 nor more than $500, or by both.

Regulating the Practice of Midwifery.—A bill, entitled "An Act to Regulate the Practice of Midwifery in Montgomery County by Others than Legally Authorized Physicians," has been reported to the New York assembly from the committee on public health. It provides for the examination and licensing of midwives who wish to carry on their calling in Montgomery County, but forbids the use by them of instruments or of any "poisonous or dangerous drug." The attempt to practise midwifery without a license constituted a misdemeanor.

The Paternal Government of our Health Board.—The therapeutists of the New York City board of health are constantly widening their sphere of usefulness, and now announce that any one bitten by a mad dog can step up to the laboratory and be cured at the city's expense. The person in charge of this new venture has reported to Colonel Murphy that "the new laboratory in the vaccine building contains every means for carrying on the treatment in the most satisfactory manner. As the treatment reduces the mortality of those bitten by rabid animals from ten per cent. or more to less than one per cent., and as there is now no place where the very poor can receive free treatment, it is respectfully advised that the department of health authorize the administration of this treatment to those who have been bitten by rabid animals and who may present themselves for treatment." Colonel Murphy has given the desired authorization, and now the press agent of the department tells the newspapers that seven fortunates from the borough of Richmond are at present under treatment, and that there is every prospect of their returning home alive. It is not said whether the dog that bit the seven was mad or only angry.

Dr. William S. Playfair has resigned from the chair of obstetrics and diseases of women at King's College, London, which he has filled for twenty-five years. It was reported that his resignation was necessitated on account of his having reached the age limit, but he says this is not so, as he has nearly four years before reaching that limit. His only reason is that, as he writes to *The Lancet*, "having completed a quarter of a century's service as professor of obstetrics, he thinks it is now high time to make way for others."

The German Balneological Society recently held its ninth annual meeting in Berlin, under the presidency of Professor Liebreich, who delivered the opening address. Among the communications were: "The Question of Contagiousness of Tuberculosis," by Römpler, of Görbersdorf; "The Effect of So-called Indifferent Mineral Waters," by Liebreich; "The Hydrotherapy of Simple Ulcer of the Stomach," by Winternitz, of Vienna; and "Vegetable Diet Cures," by Strasser, of Vienna.

The Tsarina of Russia has been ill with measles but is now convalescent.

Mr. Gladstone's Health is again a cause of anxiety to his friends. The severe neuralgic pains from which he has suffered during the past winter continue, and now the strength is failing and the heart's action is becoming very weak.

The Late Dr. E. C. Seguin.—The following resolutions have been adopted by the New York Neurological Society:

"The New York Neurological Society records with profound sorrow the death of Dr. Edward Constant Seguin, who died of cirrhosis of the liver, on Saturday, February 19, 1898, aged fifty-four years. Dr. Seguin was one of the founders of this society and its president during 1877–78, and was for many years a constant attendant at its meetings, taking a leading part in its scientific discussions, his opinions being always listened to with that respect to which his vast clinical experience and his sound judgment entitled them. For many years Dr. Seguin was placed with the foremost neurologists of the world, and his original contributions to science were valued highly.

"*Whereas*, This society has lost by the death of Dr. Seguin one of its original incorporators and an earnest supporter; therefore be it

"*Resolved*, That in his death this society has lost a valuable and honored member. In his professional attainments he was most eminent; enthusiastic in his devotion to his special field of work, in which he was justly esteemed an authority. As an author he was remarkable for his acute observation and logical reasoning, while the clearness of his style gave evidence of the directness of his thought. By his death scientific neurology has lost a zealous and successful disciple, while the community has been deprived of the services of a skilful counsellor and practitioner. The members of the Neurological Society desire thus to give expression to their feelings of respect for his memory, and, sympathizing sincerely with his family in their loss, offer them respectful condolence.

"*Resolved*, That this minute be entered upon the records of the society, and that a copy be sent to the family of Dr. Seguin and to the medical journals.

"J. Arthur Booth, M.D., M. Allen Starr, M.D., George W. Jacoby, M.D., *Committee*."

Hospitals in Need of Funds.—Several of the hospitals in the borough of Queens have become financially distressed in consequence of the new conditions prevailing since the creation of Greater New York, and it is a question whether some of them will not be compelled to close their doors. They depend for their support, as a rule, upon voluntary contributions, as few if any of them have an endowment fund sufficient for their needs. Formerly they received a liberal appropriation from the local government for their care of

indigent patients committed by the overseer of the poor, but they are now deprived of the larger part of the revenue derived from this source, in consequence of the more stringent regulations governing the care of indigent patients in New York.

The Medical Association of Missouri will hold its annual meeting at Excelsior Springs on May 24th, 25th, and 26th, instead of May 17th, 18th, and 19th, as previously announced, the reason for the change being that better accommodations can be secured at the time now appointed. The president of the society for the present year is Dr. Jacob Geiger, of St. Joseph. The preliminary programme contains the titles of fifty-two papers announced for presentation at the meeting.

The Menace of Cuba to the Public Health.—Under the slovenly rule of Spain, Havana has continued to be the worst breeding-place of yellow fever on the face of the earth, when all that is needed to put an end to it is the application of a little science to the harbor and city. Yellow-fever scares and yellow-fever epidemics cost this country millions of dollars almost annually, and yet until the insurrection is put down and intelligent government established on the island, the United States will have to suffer for the sins and neglect of their neighbors. Havana is so near to Key West that the movement of people between the two countries is quite considerable, and it is useless to deny that we have great interests at stake in the safety and well being of the island, to say nothing of the claim of humanity involved.—*The Evening Post.*

Dr. Mark Chado, surgeon-general for the past three years of the eastern division of the Cuban army under Gen. Calixto Garcia, arrived in New York on Monday last. He is here for medical treatment of the results of exposure, privation, and a bullet wound received while discharging his duties as surgeon on the field.

Foreign Students in Prussia.—A decree has been issued by the Prussian government, forbidding the future attendance of foreigners in the machinery and engineering department of the Berlin Technical High School. This action has caused much consternation among the foreign-born students in Germany, as it is believed the discrimination against foreigners will be extended to the universities in Prussia and to all the faculties, medical as well as engineering.

Pasteurized butter is the latest antiseptic novelty. It consists of butter made from pasteurized cream, and is thought to have a better flavor and to keep better than the ordinary butter.

Quarantine Physician for Baltimore.—Dr. John M. Ruhräh has been appointed quarantine physician at Baltimore in the place of Dr. G. Lane Taneyhill, who declined. Dr. Ruhräh was graduated from the College of Physicians and Surgeons in Baltimore in 1894, and since that time has been connected with this school in various capacities, and has been up to the present time head of the Pasteur Institute in Baltimore. He is especially fitted for his new position and is quite acceptable to the profession and to the public.

Johns Hopkins University.—Since the Johns Hopkins University has asked the State of Maryland for $100,000 a year for two years, there have been such strong objections to this proposed appropriation that recently by a large vote of the legislature it was refused. Fifty thousand dollars has now been asked for, and it is more likely to be given. Friends of education have fought bitterly for an appropriation, while the taxpayers, especially those outside of Baltimore, have opposed the giving of any sum at all, because they maintain that the tax rate would be raised to too high a point. Other educational institutions are now boldly asking for larger sums than they ever dared to suggest in years past.

A German Department of Public Health.—A dispatch to *The Sun* says that a movement has been started in Berlin in favor of the creation of a separate State department of medicine under a responsible minister, on the ground that the public hygiene is insufficiently protected by the medical bureau, which is merely a subordinate section of public instruction. Hamburg's cholera epidemic is instanced as a justification of the demand.

Gift to a Brooklyn Dispensary.—Mr. Henry Batterman has made a gift of $25,000 to the Bushwick and East Brooklyn Dispensary as a memorial of his daughter, Laura Frances Batterman, who died about six years ago.

Assault on Professor Grocco.—Dr. Pietro Grocco, professor of clinical medicine at Florence, was recently brutally assaulted by two men whose brother had died of tuberculosis in his ward at the Hospital Santa Maria Nuova. According to the usual custom, an autopsy was performed. When the deceased's two brothers learned of this, they went to Dr. Grocco's house, and, gaining admittance to his office under the guise of patients, set upon him and beat him very severely before assistance could be obtained.

The Tri-State Medical Society of Iowa, Illinois, and Missouri will hold its annual meeting at Dubuque, Iowa, on April 5th and 6th, under the presidency of Dr. Emory Lanphear, of St. Louis. The programme contains a long list of papers with interesting titles.

Sir William Stokes.—A fund has been organized for the purpose of presenting to Sir William Stokes, of Dublin, a testimonial to celebrate the occasion of his silver jubilee as professor of surgery in the College of Surgeons, Ireland.

The Medical-Practice Law in Maryland.—The right to practise medicine in Maryland is now restricted to those who have a degree from a reputable medical school and those graduates since 1892 who have passed the State board examination. The extreme dissatisfaction caused by the rejection of so many candidates at a recent State board examination has been the motive for introducing a new bill in the legislature. The result of this bill, if passed, would be to make the restrictions very light, especially for graduates of Maryland schools.—*Maryland Medical Journal.*

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Thirty-Seventh Regular Meeting, Held on Friday, February 4, 1898.

DR. W. GILMAN THOMPSON, PRESIDENT, IN THE CHAIR.

On Castration, with Avulsion of the Cord.—DR. ROBERT F. WEIR read a paper on this subject, and presented a patient upon whom he had performed the operation. Dr. Weir said:

"In the performance of the operation of castration for a tuberculous disease of the epididymis or of the testes, the surgeon endeavors naturally to get well beyond the disease, but in this operation his efforts are often hampered by the involvement of the vas deferens. He is therefore compelled to cut across this tube and the accompanying vessels, etc., either at a level with the external abdominal ring, or to divide the fascia of the external oblique muscle, which will then permit the removal of the spermatic cord at the internal ring. Should the vas deferens be found at this level also to present evidences of a tuberculous infiltration, the operator may, if he be a surgeon of some boldness, consider at least, even though his judgment lead him not to act, the surgical possibilities of obtaining access to the deeper parts of the vas by either the procedure of Villeneuve—which consists in enlarging the abdominal wound to, but not into the peritoneum, which membrane is then stripped from the lateral aspect of the bladder until the vesicula seminalis of that side is reached, when the vas deferens thus exposed can be divided or torn across at any selected point—or he may prefer leaving in the scrotal wound the separated testis and its bared cord with its vessels duly ligated, and then to make a transverse cut in front of the anus, by deepening which he can arrive at and pass just above the prostate gland, when a transverse incision in the investing fascial covering will expose and render easily accessible the seminal vesicle and the vas deferens. This latter can now be torn across, and upon traction then being made upon the loosened testis the whole of this tube will pull out at the internal ring like an earthworm out of its hole. Both of these procedures, however, lend additional risk to an otherwise simple and safe operation, and surgeons have justly considered it better to leave the stump of the vas deferens, even though tuberculously affected, to the resistant and curative power of the economy. Often a cure permanently occurs in such circumstances and only occasionally does an abscess at the ring or in the pelvis develop, though the eventual risk of prostatic and vesical infection is by no means small.

"With such views on this subject, and feeling the need of some safe adjunct to the ordinary method of performing this operation, I welcomed the suggestion made by Büngner, of Marburg (O. v. Büngner: 'Kastration mit Evulsion des Vas Deferens (Hohe Kastration),' *Centralblatt fur Chirurgie*, No. 46, 1893, S. 1,018), that in a castration for tuberculosis the vessels should be dissected off and thoroughly separated and tied at the external abdominal ring, and that then traction should be steadily and strongly made on the cord-like vas until it broke. In this way it was drawn out to varying lengths from the abdominal depths. Büngner reported seven cases in which he had resorted to this procedure. One patient died from erysipelas which was not specially due to the new procedure; there were three other avulsions occurring in two patients who had associated lesions of the seminal vesicles which demanded a second operation; the three remaining cases were kept under observation for a long time and remained permanently cured. Struck by the simplicity of the manœuvre and its apparent safety, I have adopted it in nine instances—making, however, a slight change in its carrying out. Instead of pulling down the vas deferens at the external abdominal ring, I prefer, after two trials of this plan, to slit up the anterior wall of the inguinal canal—that is to say, the fascia of the external oblique muscle—and thus to expose the cord and its vessels at the internal ring. The blood-vessels are now separated and tied off, and then traction is made on the vas, somewhat upward in direction or directly forward in such a way that not only is it continuous, but if any yielding occurs—and at the first pull it readily occurs—the fingers are slipped along the extruding portion so that the traction is kept up constantly at the internal ring. In this way I have torn off the cord in lengths varying from the internal abdominal ring from two to ten inches. In the last-named instances the cord separated at its ampulla, or very near to the seminal vesicle. In no patient did any mishap follow this addition to the operation of castration. In two cases the torn end still showed tuberculous infiltration; in the others the separation took place through an apparently healthy part of the tube. In only four cases has the subsequent observation of the patients been prolonged beyond one year. In these but one recurrence of the disease has shown itself, and that in the case in which extirpation of the tuberculous seminal vesicle was also resorted to.

"CASE I.—Tuberculosis of testis and seminal vesicle; castration with avulsion of the cord; extirpation of the seminal vesicle. William S——, aged thirty-two; no family history of tuberculosis. The patient had gonorrhœa several times without any complicating epididymitis; never had syphilis. For four weeks he had pain and increasing swelling of the right testicle. Examination showed this organ to be of twice the normal size, and the right seminal vesicle and right lobe of the prostate also to be affected. The organs on the left seemed normal.

"June 6, 1895, the testicle was removed and strong traction made upon the cord, which ruptured at the seminal vesicle and came out entire. It was found to be tuberculous clear to its end. The patient was therefore put in a lithotomy position, and through a transverse incision, made just in front of the rectum, the prostate gland was exposed. There was free bleeding. The recto-vesical fascia was cut through transversely just above the prostate, and the enlarged right seminal vesicle freed and removed. A tuberculous nodule in the right lobe of the prostate was removed, causing a small opening into the urethra. A glass drain and iodoform gauze packing were placed in the wound. A catheter was employed twice a day. No urine escaped through the perineal wound until the third day, when catheterization was discontinued. This flow ceased in a short time, and the patient was discharged in two weeks.

"The report of the pathologist was as follows: 'The entire vas attached to testis, twenty-eight centimetres long; one seminal vesicle and part of the prostate, four to eight millimetres in diameter; and six centimetres more (eight millimetres in diameter), attached to seminal vesicle, were removed. Vas everywhere thickened, rigid, lumen occluded, with many distinct cheesy areas.'

"CASE II.—Double castration with avulsion of both vasa deferentia; insertion of celluloid testicle. John H——, aged twenty-five, suffered for ten months with swelling and pain in the right side of the scrotum. About the middle of June, 1896, fluid was drawn from the distended right tunica vaginalis. Six months later

there was a small recurrent hydrocele of the right side, that testicle being also hard, while the left one was both hard and nodular. The cords were not involved. The patient gave an indefinite history of syphilis. The lungs were normal.

"At operation, December 16, 1896, both testicles were found badly diseased, and with the cords were removed by traction. A celluloid testicle was inserted on the right side. There were primary union and a perfect recovery.

"The vasa removed were fifteen centimetres long and included the beginnings of the seminal vesicles. The testicles contained numerous areas of necrosed and pus deposits. Giant cells were found, but no tubercle bacilli, and a diagnosis of syphilis was made. The patient was seen eighteen months later. The celluloid testis was well borne, and the general health was excellent; sexual vigor was reported satisfactory.

"Case III.—Single castration and avulsion of vas deferens for tuberculosis. Stephen McC——, aged twenty-eight, gave a history of swelling and pain in the left testicle, of two years' duration, with a sinus for six months. The cord was not apparently affected. There was also a smaller induration on the right epididymis. There was slight induration at the apex of the right lung.

"October 16, 1896, under ether, the left testicle was exposed and with the left cord pulled out three or four inches and torn off. A celluloid testicle was placed *in situ*. The wound was sutured and through a separate incision the nodules in the right epididymis were excised, and this wound also was closed. On account of a hemorrhage from the stump of the cord the wound in the left side was opened the following day and the bleeding controlled. The celluloid testicle which thereby escaped was not replaced. The examination of the left testicle and of the tissue from the right one showed the characteristic lesions of tuberculosis to be present. Recovery was slow, and at discharge from the hospital, three weeks later, there was still a slight sinus on the right side.

"Case IV.—Double castration with avulsion of both cords; insertion of a celluloid testis. Eugene S——, aged twenty-seven, was troubled for four months with swelling and pain in both testicles. Recently a sinus formed in the right side of the scrotum.

"December 23, 1896, both testicles were found to be hard and nodular and increased in size. Both cords also were hard. By an incision over the left external ring, the testicle of that side was drawn out and traction made upon the cord until it came away, separating at or near the seminal vesicle; on each side fifteen inches of the vas was removed. The tubes were normal at their torn ends. On the right side an elliptical incision included the sinus, and the testicle and cord were removed. Celluloid testicles were inserted in both sides of the scrotum. The left one healed in; on the right side suppuration occurred and the celluloid substitute came out. Six weeks later the patient was in good condition, but power of erection and desire for intercourse were lost.

"Case V.—Castration for tuberculous testis; avulsion of cord; insertion of a celluloid testis. G. C——, aged twenty-one, had been a sufferer from scrotal trouble for over three years, and in 1895 the left testicle had been removed for tuberculosis. A few months later pulmonary lesion developed. Four weeks ago the right testicle swelled and became tender, hard, and nodular. The prostate was apparently not involved.

"On April 8, 1897, the testis and cord were dissected out and the vas was separated and pulled upon till it broke, ten centimetres from the testis. It showed where torn across, tuberculous infiltrationon microscopic examination. A celluloid testis was afterward inserted, and primary union followed the operation. Six weeks later the patient was seen in good condition.

"Case VI.—Castration for tuberculous testis; avulsion of vas deferens; insertion of a celluloid testis. Herbert R——, aged thirty-one years, entered the New York Hospital, October 12, 1897, with the history that eighteen months ago he had the left testis removed in the ordinary way, and that ten days ago the right testis became painful and swollen, without any urethral discharge.

"On October 14, 1897, the right testis and vas were removed, the latter by traction, and the cord broke about two inches inside of the internal ring. A celluloid testis was placed in the scrotum, with subsequent primary union. Discharged cured, October 22, 1897. The pathologist's report was tuberculosis of epididymis.

"On January 20, 1898, the patient returned for inspection. He was in good health; he said he had occasional sharp pain in the right inguinal region at night; had also some flushing and sweating; had erections and sexual congress about every two or three weeks. He said he had a sensation as of no ejaculation. Erection was slower and not so complete as before. He gained in weight.

"In five of the foregoing cases, and especially when a double castration either in one operation or more commonly when a second castration eventuated, I have, for the mental effect and in response to the generally uttered request of the patient to save if possible some of his testicular substance, replaced the damaged organ by a celluloid testis somewhat of the size and shape of the normal organ, with much after-satisfaction to the patient, and, I may add, occasionally to the deception of a professional brother, for once such an artificially supplied patient was sent again to the hospital with the diagnosis of tuberculous testis and a request for a castration.

"This substitution has been employed in six other non-tuberculous cases—eleven times in all—once as a double replacement in a castration for hypertrophy of the prostate (in which, I may say, there was no improvement in the prostatic difficulty, for which the artificial testes were responsible in keeping up false hopes, a colleague jocosely remarked); and in no instance have the foreign bodies begotten any irritation, and they have in four instances been retained for over eighteen months. In two additional instances, from wound contamination from escaping tuberculous pus, failure of skin union occurred and permitted the escape of the celluloid piece and its cognizance by the patient. A scrotal hemorrhage in one instance brought about a similar result. In the last case, in which a second castration was necessitated and in which a celluloid testis was inserted, a point of some interest has been developed. Under careful questioning this patient whom I exhibit to you to-night states that he still has decided sexual power, though his congress occurs but once in two or three weeks, and it is not accompanied by his previous sense of seminal emission. He further intimated that he yet strongly relied upon the power which his preserved (a celluloid) testicle gave him. His sexual ability is alluded to only to illustrate the mental effect that this innocent procedure of celluloid substitution brings about and is of but little importance quoad his virile powers themselves. For there are many cases, from Astley Cooper's down to the present time, that show that after a loss of both testes impotence may be delayed for a period as great as nine years; but what is of more importance to know is that under such circumstances it may happen, though rarely however, that from a congress soon after the operation fecundation may happen from the spermatozoa formed and left in the vesiculæ seminales prior to the double or last castration."

A Case of Hemorrhage of the Cord; Paraplegia.—Dr. W. Gilman Thompson presented a man, thirty-five years old, who, on August 29, 1897, while walking in the dark, fell and struck on the back of his head and neck. He was unable to rise, and lay without assistance until the following morning, when he was brought to Bellevue Hospital. An examination showed that he was suffering from paraplegia, both arms and legs being totally paralyzed. There was no disturbance of sensation, excepting for an area of hyperæsthesia over the chest, and there was no anæsthesia. There were no reflex disturbance and no vesical or rectal trouble. Over the fifth cervical spine crepitus was elicited, which seemed to be due to a fracture of the spinous process. The paraplegia remained absolute for two or three days; then power gradually returned, first in the arms and after several months in the legs. Recently the man had complained of a girdle sensation around the upper part of the thorax, and then lower down. Dr. Thompson said the case had been diagnosed as one of hemorrhage into the cervical cord, the blood clot having been gradually absorbed. No operation had been thought advisable. The case was interesting on account of the excellent recovery which the man had made after the onset of such a complete paraplegia.

Our Counsel to Patients, Especially in the Later Part of Active Life.—Dr. Henry F. Walker read this paper. He said:

"There is a saying that when a man has reached forty years he should be his own physician, and there is much truth in the adage. Experience should have taught him the care which is the preventive of disease. And a physician's observation proves that this is the fact. His practice is chiefly among the very young and the adolescent, with occasional severe illnesses in such natures as are strong by heredity, and a more constant attendance on those whose strength is ever crippled by inheritance of infirmity.

"Before forty, a man may need direction; after that, he should get on with advice. Experience has taught him what it is possible to do in given circumstances; but the most changeable thing is himself. That factor in the situation is an element in reference to which keenest judgment is apt to be in error. When a youth, he considered himself mature, while others were callow; at a later date he calls himself young, though his contemporaries are old. The hardest thing that he is compelled to realize is that changes occur in himself; that a thing which he has heretofore done with impunity may in time become hazardous in repetition. The morning cold plunge, the going without an overcoat, the refusal of extra footwear—any or all may become hazards to health.

"If a man be really aged, exposure to cold no longer invigorates. For him, protection against external cold must be greater and the house must be warmer. Warmth is better than exercise, and abstinence better than such an amount of food as makes exercise imperative. It is often quite difficult to persuade an aged person or his friends that exercise in the open air is not absolutely essential to well being, or that the fireside is more invigorating than the cutting wind of a brilliant winter day. They quote experience against you. Having always done a thing with advantage, they can do it still, unmindful that the personal equation has changed, and that an element once a friend to buffet may become a foe that kills.

"Of the elements the one the most harmful to the aged is cold. They starve with it, to use the old English phrase. But luckily it is the element we can most successfully guard against. We can maintain fitting bodily warmth by clothing, and at night, at least, we can regulate the temperature of the air we breathe. To the old, as well as to the very young, a mild heat for the sleeping-room is better than the haphazard temperature given by an open window. That he has always slept with the window open, no matter what the weather, is boasted by a man who demands an overcoat and a fur cap in waking hours, without seeing his inconsistency. There is a great deal of nonsense talked about the need of fresh (meaning open) air in the sleeping-room. You can constantly cherish a catarrh with it. Nansen, in his sleeping-bag, has proved that one can survive and thrive with a modicum of it.

"But the hazards to which the man who has reached the time when he should be his own physician is exposed are less those of external than internal origin.

"He is past the time when he would be backed for a contest in the prize ring, and that means that he is past the time of greatest physical vigor. Of course there are compensations. To counterbalance diminished physical force, he has higher intellectual attainments and a greater capacity for mental labor, by dint of training and experience. But experience and training have brought with them greater demands upon his strength. If a man of ability, he has the burdens of others to carry, as well as his own. The willing worker has always enough to do for others. Each year adds to responsibilities which he assumes through his own or others' necessities, or by choice through ambition. And each year gives him a body a little less in strength by which to carry them. The change may be slight, but it is actual. The consequence is that with increased work and weakened body, aid which is harmful is often sought. There are two things which threaten such a man's comfort: half or wholly recognized diminished physical strength to do increasing work, and the inability to get abundant sleep or enough sleep for full refreshment.

"I think that the greatest hazards to a man's character are likely to come after he has passed forty-five years of age. He has become more lenient in his judgment of others, and is likely to be more indulgent to himself. To speak of things wholly physical, he has then the temptation to both stimulants and narcotics (or hypnotics) in the highest degree. And those temptations come to him when he is acting, chiefly, as his own physician. If a young fellow becomes a drunkard before he is thirty, and goes to the devil prematurely, you can usually find for him the plea of heredity. But there is many a man who has passed thirty years and forty safely, who in the next decade succumbs to alcohol because he needs a brace to help him transact the business which the close work of previous years has brought to him. He takes to alcohol, not in the convivial way, but to help him over a hard place; and he takes it in just the worst manner, without accompanying food, and when food would likely be distasteful, or even harmful, by nervous preoccupation. The afternoon drink to tide him over a weary day joins to itself earlier potions when business presses, and the morning cocktail before it has begun. And all this is due to the overwork given to the man whose established character has brought him to the front. If a man passes in safety the time when strength declines without his realizing the fact, and reaches the time when he must acknowledge it, he is all right.

"If it be not alcohol alone that is used, it is alcohol with a subtle stimulant more deadly, a coca, or a kola, which obscures the immediate effect of the medium.

"The other hazard is the use of hypnotics. Of course these are of various degrees of potency and harmlessness. But you will find that the man who consults you for insomnia knows the list and has tried them all before he has applied to you. You are very fortunate if you are one coal-tar product ahead of his experience. Acquaintances prescribe for one another, so that the physician is only a consultant as to the

least harmful of such drugs. There is no one of them but has been made a habit, and the patient is lucky to whom morphine has not been the false friend. We have all had patients who have had the bromide, the sulfonal, the trional, or the chloral habit; and, if there be a hypnotic that does not claim its victims, it is because it has too recently graduated from the laboratory.

"Now, granting these premises, I believe that there is a line of duty which belongs to the physician, as regards his patient, which is clear. There is counsel to be given, which is more like that which his priest would give than is usually the function of the doctor. Unluckily, in these days, when we recognize a patient as ours only so long as we are pocketing his fee, there is less opportunity for guarding his vices and his virtues than aforetime. But still we have chances, if observant.

"One thing to be emphasized is that each man has his own physical limitations. It is no criterion for him that some man has been able to do more, or that the average man does more. He must abide by his own capacity. Another is that in physical power first is shown decline in strength. Luckily in many things taste changes, and nature aids a man to bear such physical change by change of sentiment. The boy cannot pass a hydrant without vaulting it: but the man walks by it tranquilly many years before he shuffles past it. Another is that hours taken daily from active business and devoted to muscular play, usually called "active exercise," are not to be reckoned as misspent time, but guarantees of health; and, as corollary to this, that each successive year the leisure time should bear a greater proportion to the time of hard work, and the vacation should be looked upon not as a luxury but as a necessity; that is to say, rest is cure. Another is that stimulants are stimulants only and do not add to real vigor, but are ever productive of harm; while a man's capacity for work should be estimated by himself as what he can do without the whip and spur of alcohol. Another is that for the hours of diminished sleep which come in the train of increased birthdays there should be cultivated a habit of tranquil rest, to take their place and give its refreshment. And this can be done if sleeplessness has not its frequent yokefellow—worry."

Dr. Beverley Robinson said he would refer to only one topic of Dr. Walker's paper, *i.e.*, the use of alcoholic stimulants by persons of more or less advanced years. In many such individuals there were arterial changes which were nothing more than should be expected at such an age—which were, in fact, a normal expression, and the speaker said that in his opinion they would not warrant the cutting off of alcoholic stimulants, for fear that the alcohol might be productive of injury in some organ, more particularly the brain. Men of a certain type, when they grew old, must have a certain amount of alcohol in order to assimilate their food properly.

Dr. W. H. Draper said he had been interested in listening to Dr. Walker's paper, which contained the sound philosophy that a man of ripe experience was ever fit to give. By the age of forty a man ought to have discovered what was good for him and what was evil, but people were very apt to forget. As regards the use of alcoholic stimulants, to which Dr. Robinson referred, the speaker said he did not suppose that it was Dr. Walker's idea to interfere with the habits of patients which he found to be beneficial to the health of the individual. The habit of using alcohol in moderate quantities was one that most people acquired as they grew older, because they began to feel the encroachment of age, and to make them desist from its use under such circumstances would be altogether contrary to the spirit of Dr. Walker's paper. Of course there could be no question in regard to the evils resulting from the continuous use of narcotics or preparations of opium, which were not so directly hypnotic as they were anæsthetic.

Dr. Walker, in closing, said he was fully in accord with the statement made by Drs. Robinson and Draper, that a man, as he grew old, was ofttimes benefited by the use of alcohol, taken in a proper way. What he objected to was alcohol taken at odd times. A man of forty or over was very apt to be better for the use of stimulants taken with his meals, but it was the drinking between meals that did the harm.

Nitrous Oxide and Ether for Anæsthesia.—Dr. V. P. Gibney read this paper. He said:

"Early last fall at the Hospital for the Ruptured and Crippled, my attention was called to the advantages of nitrous oxide and ether as an anæsthetic. After a few observations I was so fully impressed with this combination that it was decided to adopt this as the anæsthetic for the operating-room. It was administered by a skilled anæsthetist, and this may account in a measure for the success which we have had.

"The children in the hospital have always had a dread of ether, and have for a long time been in the habit of asking for gas in preference to ether. Whenever assent was given, the fears of the child were allayed and we were able to proceed with very little difficulty. In the combination we have experienced no unpleasant results whatever; we have been able to avoid the disagreeable choking sensation and the struggling, even in the most timid of children. Indeed, the hospital staff has become quite enthusiastic over gas and ether.

"It is not my purpose in this communication to give any statistics as to the length of time required to produce complete anæsthesia, the condition of the urine before or after its administration, but simply to call attention to the ease and the rapidity, in a general way, with which the patient can be anæsthetized.

"The junior assistant no longer has charge of the anæsthetic, but he is coached, so to speak, by the instructor in anæsthesia. This position is filled by Dr. Thomas L. Bennett, who has been regularly appointed by the board of managers, and who attends on all operating-days, noting closely all the points for observation, examining the patient before operation and giving an opinion as to the kind of anæsthetic that is best suited for the individual case, and then giving assurance to the operator.

"Inasmuch as many members of the Practitioners' Society have already used this combination, I shall make my remarks brief. It is not a new method; it has been used for at least twenty years in England, and appliances are already in the market for its administration. Clover, for instance, has a gas and ether apparatus. The gas may be given to the production of complete anæsthesia, and then the ether may be rapidly given by means of the Ormsby inhaler. In some instances when the Clover is employed, the gas is given to the point of unconsciousness, and then both ether and gas are given until complete anæsthesia is produced, when the ether only is continued. Within fifteen or twenty seconds this period of unconsciousness can be obtained by proper administration of the gas, and the patient is ready for operation in from two and one-half to four and one-half minutes.

"My personal observation leads me to state quite positively that there is no stage of excitement. There is very little mucus found, and, above all things, there is very little ether administered. All surgeons are unanimous in recommending that the minimum amount of ether should be employed and that a stage of complete anæsthesia should be reached as quickly as possible. With children this is especially true, and, while I institute no comparison between the administration

of chloroform and ether, I feel quite sure that a young child can be brought under th influence of the combination of gas and ether as quickly as under chloroform. A few years ago it was thought that chloroform was perfectly safe in children; now the opinion is not so extensively entertained.

"In the *Practitioner* for October, 1896, Bailey discusses the principles of ether administration and refers at length to the combination method which I now advocate.

Dr. George F. Shrady said that he had no personal experience with the method of anæsthesia described by Dr. Gibney. He had been somewhat prejudiced against nitrous-oxide gas on account of the alarming symptoms of carbonic-acid poisoning it sometimes produced. The speaker said he had never had any trouble in getting people rapidly under the influence of ether. Some years ago he had had occasion to have ether administered to himself twice, the first time by the "difficult" method, and the second time by the "easy" method, and this experience had impressed him very much with the value of the latter, which consisted in giving the patient a hypodermic injection of morphine about fifteen minutes before etherization was undertaken, and then coaxing the patient and quieting him, up to the stage of primary anæsthesia. If this method was carefully carried out there would be little or no struggling. The possibility of struggling, however, should be borne in mind in the preparation of the patient. Dr. Shrady said that formerly he generally employed chloroform in operations on children. About three years ago, however, he had a case in which the child nearly died from the effects of the chloroform, and since then he had almost invariably used ether, both for the young and old. In conclusion, the speaker said that if the method described by Dr. Gibney could be safely relied upon to shorten the period of anæsthesia it would certainly prove a very desirable improvement.

Dr. Robert F. Weir said that several hospitals in this city had lately shown their appreciation of the importance of the proper conduction of anæsthesia by appointing a competent man, whose duty it was not only in special cases to anæsthetize patients but also to instruct the junior physicians how properly to administer the various anæsthetics. This, the speaker thought, was a most desirable innovation, as the giving of ether or chloroform by an inexperienced assistant had often given rise to much anxiety in the surgeon's mind. The method of anæsthesia described by Dr. Gibney, namely, nitrous-oxide gas followed by ether, was an old one. It was probable that the gas would be more generally employed were it not for the fact that its administration required a certain kind of apparatus which most surgeons did not possess. The gas sometimes gave rise to apparently alarming symptoms, but still it must be looked upon as a very safe anæsthetic, as death following its use was very rare. The asphyxia it caused was sometimes so profound as to cause anxiety, and one or two accidents had been reported by dentists, which were probably due to the faulty position of the patient, in being allowed to sit up during the anæsthetization, or to the fact that a certain amount of chloroform was mixed with the laughing-gas. As regarded the relative safety of ether and chloroform, there could be no question as to the advantage of the former. Dr. Weir said he could recall only two deaths from ether, in his experience. One occurred after the sudden reduction of a large hernial mass which had been allowed to remain unreduced for years and had become partially incarcerated, and thus might have interfered with the diaphragm and heart movements. The second was due to matters vomited from the stomach in an urgency operation. Dr. Weir further remarked that in a recent number of the *British Medical Journal* there had been published an important article by Waller, giving the results of his investigations of the action of chloroform and ether on the nerves of the body. This observer stated that ether impaired the function of the nerve only temporarily, while with chloroform the nerve not only became impaired more frequently but it remained permanently disabled seven times more commonly than from ether, and that its function failed to return. This perhaps gave a clew to the action of chloroform, and why patients who suffered from marked heart collapse during chloroform anæsthesia could so seldom be resuscitated. It was for this and other reasons, Dr. Weir added, that he was loath to employ the mixture of chloroform and benzin, recently recommended by Schleich and others, and gathering experience had shown that this combination was not so free from risk and mishaps as had been anticipated.

Dr. F. P. Kinnicutt said he had seen Dr. Bennett administer gas and ether in the manner described by Dr. Gibney, and it certainly seemed to rob anæsthetization of many of its disagreeable features. The patient was anæsthetized in about fifteen or twenty seconds, and there was no period of excitement. Another advantage was the small quantity of the anæsthetic that was required.

Dr. George L. Peabody said that nitrous-oxide gas acted by producing asphyxia. Its action differed from strangulation only in that it allowed the movements of the chest and heart to go on. The gas was non-irritating, but as it acted by depriving the system of oxygen its administration should not be continued for any length of time. As regarded the excitement often witnessed in the early stage of ether narcosis, the speaker said he was quite sure that this was largely attributable to terror on the part of the patient, and could often be obviated by explaining to him beforehand that the ether gave rise to a feeling of strangulation, which need cause him no alarm. If the patient's confidence could thus be gained and the anæsthetic be given at the start not too energetically, he would usually take it quietly; otherwise he was apt to struggle, because he thought there was something peculiar about his condition.

Dr. Charles L. Dana said that, while the statement made by Dr. Peabody regarding the physiological action of nitrous-oxide gas had apparently been demonstrated in the laboratory, he did not think that it explained the clinical fact that this gas undoubtedly produced exhilaration without any attendant symptoms of asphyxia. The experiments of Waller, which were referred to by Dr. Weir, seem to prove also that the gas had a specific effect on the nerves.

Dr. W. H. Draper said he had recently seen Dr. Bennett administer nitrous-oxide gas in combination with ether to a woman who was very nervous about taking an anæsthetic, owing to the fact that she had witnessed the etherization of her husband some weeks before, when he had been operated on for appendicitis. She was requested to breathe the nitrous-oxide gas, and within twenty seconds she was unconscious and not seriously cyanosed. The ether was then given and in less than four minutes she was ready for the operation, which was completed in a short time, not more than one ounce of ether having been required. She recovered from the effects of the anæsthetic very quickly.

Dr. Beverley Robinson inquired whether the inhalation of nitrous-oxide gas could be prolonged for any length of time with safety, and also whether it was necessary to caution the patient to abstain from taking food previous to its administration. In one case that had come under his observation the gas was administered to a man who was to undergo an operation for hemorrhoids. It was found necessary for

some reason to prolong the operation for quite a while, and since then the man had suffered from certain cardiac symptoms which the speaker thought it possible were attributable to the prolonged use of the anæsthetic.

Dr. Weir said that, while apparently in many operations under ether a large quantity of the anæsthetic was employed with the ordinary impromptu cone, the fact should not be lost sight of that by the usual methods of anæsthesia much of the drug was wasted. Many years ago Dr. Squibb and himself had investigated this subject, and they found that with carefully arranged cones, which admitted only a small amount of air, two or three ounces of ether were usually sufficient for an ordinary operation, and that by the coarser methods the patient, as a rule, did not get more than three or five ounces from the half-pound can that was usually employed; the rest was wasted.

Dr. Gibney said he did not think it was customary to give the patient any directions about taking food before the administration of the gas. As regarded the length of time that the inhalation could be continued with safety, Dr. Bennett had informed him that the anæsthesia could be prolonged for half an hour or longer. The speaker said he had seen several cases in which the patient was kept under the influence of the gas for twenty minutes; when the patient became a little livid, the gas was shut off for a moment and oxygen substituted. Patients recovered from the effects of the gas in a remarkably short time.

Dr. Weir said that in one instance he had kept a patient under the influence of laughing-gas for an hour and a quarter, giving him, of course, occasional whiffs of oxygen, and that he had witnessed a case in which etherization had been continued for nineteen hours, to permit continuous and quiet pressure on a femoral aneurism.

Dr. Francis P. Kinnicutt presented a post-mortem specimen in connection with the following case. On February 1st there was admitted to his wards in the Presbyterian Hospital a young man, who apparently was in vigorous health, aside from exhibiting slight hoarseness and a very moderate degree of dyspnœa. The patient stated that these symptoms had existed only for a day or two, although he admitted that he had been treated for some throat trouble previous to the appearance of the present symptoms. There was no cyanosis, and the heart and lungs were free from disease. There was considerable swelling of the neck in front, and this, so far as one could judge, was limited to the perilaryngeal tissues. There was no enlargement of the cervical glands, and the thyroid was not enlarged. There was no appreciable local sensitiveness on manipulation. It was impossible to obtain a laryngoscopic examination of the interior of the larynx on account of the faucial irritability. The epiglottis, however, was seen and was not œdematous. During the night following admission, there was very little dyspnœa. On the following morning the patient suddenly cried out that he was choking and died almost immediately. He was intubated in the few moments which elapsed before death, but without avail.

Autopsy: There was an indurated swelling of considerable size on the left side of the larynx. The left aryteno-epiglottic fold was greatly swollen and indurated and projected beyond the median line so as to overhang the glottis. The left vocal cord was also much thickened and the left ventricle was obliterated. In the sinus pyriformis on the left side was a cut or laceration of the mucous membrane about one-half inch long. This formed the opening of a ragged sinus or pouch extending nearly three inches downward at the left of the thyroid cartilage. The inner wall of this sinus was ragged and sloughing, and it contained a reddish purulent fluid of foul odor. The left crico-thyroid articulation had broken down, and the inferior cornu of the thyroid appeared to be necrotic and crumbling. Nearly the entire left half of the thyroid was covered with sloughing tissue. The cartilage was not denuded.

Microscopical examination: Smears of pus showed no tubercle bacilli. Seven sections, each from a different part around the sinus, showed the lesions of simple inflammation.

Dr. Kinnicutt said he was unable to account for the lesion except on the theory that the rent described in the report of the autopsy had been made by some instrument and that the sinus and inflammatory changes had occurred as the result of the injury. Death was evidently caused by a sudden and complete occlusion of the glottis, which might easily have occurred in view of the tissue lesions described.

Dr. Beverley Robinson said that some of these cases of sudden death from occlusion of the glottis might be attributable to angina Ludovici. He referred to one case of fatal œdema of the glottis complicating erysipelas.

Dr. Shrady was inclined to think that the immediate cause of death was œdema of the glottis. The œdema might have disappeared before the autopsy was performed.

Dr. Janeway suggested that the œdema might have been dispelled by the pressure of the intubation tube.

Dr. J. W. Brannan expressed the opinion that such a serious laceration of the aryteno-epiglottic fold would have given rise to more prominent symptoms than this man showed previous to the onset of the fatal dyspnœa.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENT, PHARMACY, PUBLIC HEALTH, RIVER POLLUTION, PLAGUE—MEDICAL SOCIETY, ABDOMINAL SECTION FOR MEDICAL CASES—CLINICAL SOCIETY, LAMINECTOMY, LUPUS—MEDICO-CHIRURGICAL ANNUAL MEETING—CAMBRIDGE MEDICAL SCHOOL—MIDDLESBOROUGH EPIDEMIC, DEATH OF THE HEALTH OFFICER.

London, March 4, 1898.

Bills to amend the public-health acts and the pharmacy acts have been brought into Parliament, but neither seems likely to make much progress. The promotors of the rivers-pollution act hope to get a second reading of their bill early. So do those interested in an habitual-drunkards bill. Sir W. Foster elicited that an unpublished rule had prevented three army medical officers obtaining promotion, because, being over fifty-seven years old, they would not be able before sixty (when compulsory retirement takes place) to put in three full years in the higher grade. A retrospective and secret rule is thus the means of doing injustice to the medical service, and the minister who had to defend this had to acknowledge that the army service is practically boycotted by the profession. We may hear more when the vote for the service comes up. The midwives question threatens to become most serious, and the danger becomes more grave of an inferior order of practitioners being established. Lord Onslow announced that for the first time for ten weeks the government telegram showed an improvement in the plague mortality of Bombay. He also said the results of the Haffkine serum were encouraging. But you will get news on this subject from other sources.

The advance of the surgeons into the territory of the physicians continues with surprising success and

determination. On Monday the Medical Society's meeting was given over to the surgeons for the discussion of a paper on "Abdominal Section as a Medical Measure." Mr. Treves, the author of this, began by remarking on the difficulty of defining a medical case and distinguishing it from a surgical one, and it would appear that when in doubt he would decide for surgery. It reminds one of the old definition by a surgeon: "If the patient brings a fee, the case is surgical; if he cannot pay, it is medical—recommend him to a physician." But to return to the paper. Mr. Treves mentioned the well-known fact that in certain cases the abdomen had been explored and no abnormality found, but nevertheless amelioration of the symptoms, if only temporary, had followed the operation. The results of an incision in tuberculous peritonitis had certainly been most surprising and must have been exceedingly gratifying to those whose erroneous diagnosis led to operation. Other conditions were mentioned as sometimes benefited by a simple incision—among them, pyloro-phlebitis and malignant growths. These latter had shrunk after operation; at any rate, temporarily. Nervous cases, such as those which had been termed "intestinal hypochondriasis," were also held to be amenable to operation, but certainly occupied a position very different from that of tubercle and malignancy. They were said often to follow chronic colitis and simulate stricture, and a contracted state of the sigmoid flexure had sometimes been found.

When Dr. Brunton rose, it was anticipated he would defend the position of the physicians, but he abandoned it completely, and suggested that the time would come when the abdomen would be opened, not only for tuberculous peritonitis, but for pulmonary phthisis. He said that a woman in advanced phthisis, who had a large cavity in one lung, suffered so much from pain in the abdomen that she insisted on its being opened, and after the operation the pain was relieved, and, further, the pulmonary condition improved, as did the general health. The explanation, he suggested, might be that the admission of air brought about the production of large quantities of an antitoxin, though how it should do this he did not say. He further mentioned that a medical man suffered such severe pain in the abdomen, coming on at night, that he determined to have an exploration made. Adhesions were found on the side opposite to the pain. After the operation the pain did not return, but the case was too recent to justify definite conclusion.

Mr. Bryant deprecated too free explorations, though he mentioned two cases in which he had been induced to operate, and no ill result followed. One was for what the obstetrician declared to be an undoubted case of ovarian tumor, though when the abdomen was opened nothing could be found. In the other case, on coming down as he supposed to the peritoneum, he was unable to dissect it off and gave way to the obstetrician, who was confident that it was not peritoneum. Consequently he proceeded and cut into the intestine. No harm resulted, and eighteen months afterward the patient continued pretty well.

Dr. F. J. Smith asked whether surgeons thought it would be justifiable to evacuate ascitic accumulations by incision instead of by tapping.

Mr. Alban Doran suggested that the cases which had been mentioned were probably cases of old tuberculous peritonitis or cyst of the urachus. He mentioned a case of fæcal vomiting following symptoms of irritant poisoning. He thought the symptoms might be due to the coincidence of irritation and obstruction.

Mr. Treves said fæcal vomiting was exceedingly rare, a mass of casein being often mistaken for fæces.

Some interesting cases were exhibited at the Clinical Society on Friday last. One was a recovery from pressure paraplegia after laminectomy. The patient, a girl of twelve, had spinal curvature, and pressure symptoms came on eighteen months before admission. In December, 1895, the laminæ of the four upper dorsal vertebræ were removed. In July, 1895, no benefit had accrued, but two months later sensation began to return; motor power was gradually restored, and now she can walk several miles. Another patient was shown, a man of forty-eight. He had complete paraplegia and prominence of the lower dorsal vertebræ. Three laminæ were removed. In ten days pain had disappeared and power began to return in the legs in three weeks. A girl of five was also shown, who had been treated by Calot's method, in September, 1897, for paraplegia from caries in the upper dorsal region. Within a week movement in the legs began and progress was steady. The jacket was removed February 18, 1898, and she can now run, walk, and jump without pain. This is the first case shown to the society after removal of the plaster jacket.

A case brought forward as lupus of the nose, treated by TR tuberculin, gave rise to some difference of opinion. Some of the members were disposed to consider the case as one of syphilis, of which there was a history. It was stated that there had been a node on the skin, the result of a blow, and that for this iodide of potassium had been given about the time the patches began to heal. On the other hand, it was said that the reported chancre might have been a patch of lupus. After each injection the temperature rose to 102° F., and remained at 100° F., and the question arises whether this reaction is of diagnostic value—as it is supposed not to occur in syphilis. The case at best must be regarded as doubtful.

The annual meeting of the Medico-Chirurgical Society was held on Tuesday, when the president, Dr. W. H. Dickenson, delivered an address, reviewing the work of the year and mentioning those fellows who had died in that period. These were mostly mentioned by me at the time. The reports of the council and committees were adopted. The treasurer's statement shows that the finances are satisfactory; £422 has been spent on new books for the library.

An influential meeting of Cambridge men was held in London on Tuesday, in connection with the need for new buildings for the Medical School at Cambridge. It is necessary to raise £20,000, and the vice-chancellor said nothing could be had from the university chest, which he had percussed recently, eliciting so loud and clear a note that the veriest tyro would recognize it as absolutely tympanitic. It was agreed to form a committee of graduates to take steps for the advancement of the school. Dr. Dickenson, who had presided, was appointed chairman of the committee, and Dr. Norman Moore and Mr. Herbert Page were named as secretaries.

The Middlesborough epidemic of small-pox has extended all through the week. The new cases per diem have varied from twenty-seven to sixty-five. A very large number have been in houses previously free. There is now hospital provision for six hundred, and two hundred beds will be used if necessary in a local asylum which has just been built. The number of cases notified to the end of February was six hundred and eighty-five, and one hundred and thirteen have thus early been added for March.

I am sorry to hear that the medical officer of health, Dr. Malcomson, died on the 1st inst. It is said his death was hastened by the overwork and anxiety caused by the epidemic.

Suppurative Inflammations.—Sodium bicarbonate in a two-per-cent. solution invariably stopped the pain and the suppuration and effected a rapid cure without drainage.—GEORZENSKY.

OUR BERLIN LETTER.

(From our Special Correspondent.)

RATIO OF PHYSICIANS TO POPULATION—TOO MUCH IS BAD FOR THE HEALTH—HERMAPHRODITES—MILIARY TUBERCULOSIS—THE HEREDITY OF DISORDERS OF SPEECH—CONGRESSES.

BERLIN, February 28, 1898.

THE statistical data bearing upon the ratio between physicians and the general population of Germany, as given out in the new edition of the "Deutsche Medicinal-Kalender," are interesting. We learn that there were 24,873 physicians in the empire during the year 1897; a ratio of 4.5 physicians to 10,000 inhabitants. In 1883 the ratio was 3.33 to 10,000; in 1890 it was 4 to 10,000. Thus 1897 shows a decided increase. Berlin, with its 1,750,000 inhabitants, has 2,196 physicians, or 1 to 800. Ten years ago there was but 1 physician to 1,218 inhabitants. This is an increase of almost eighty per cent. In the mean time the population increased but nine per cent. Throughout the entire empire there exists a similar disproportion. When we furthermore learn that during the first years of the last decade there was a slight falling off in the number of medical students, which, however, has since been surely and steadily increasing, we cannot but conclude that there is a most unwholesome overproduction of physicians. France has from 26,000 to 27,000 physicians; Paris, with its 2,500,000 inhabitants, has 2,500, or 1 physician to 1,000. England, on the other hand, has but 20,000.

This overproduction of physicians explains why medical life in Berlin is as active as it is. It also explains the eagerness with which so many press to the front; why there is such a continuous effort to advance medical science. But then "too much is unwholesome," and an overactivity works injuriously in the end. An example which illustrates this saying is given us by the Berliner medicinische Gesellschaft. As a consequence of the increase in number and length of the demonstrations before the regular order of proceedings of the meetings, this latter was usually greatly encroached upon and curtailed. Many who had come fully prepared and who were announced on the invitations, could not read their papers and were even compelled to postpone the reading for several meetings. With a view of remedying this evil, it was decided to permit those demonstrations only which were previously announced, and, furthermore, to open the meetings on demonstration evenings three-quarters of an hour earlier. This works well, and now everybody is satisfied.

The demonstration of cases of hermaphroditism formed one of the features of special interest at the last few meetings. Dr. Bruck showed an Italian who passed as a man, but who was shown by means of an *x*-ray photograph to have a female pelvis. Professor Hansemann demonstrated a number of specimens of hermaphroditism which had in the course of years accumulated at the Friedrichshain Hospital. Virchow participated in the discussion. Most hermaphrodites, he said, belong to the female sex. But one case of genuine (true) hermaphroditism—that is, an individual in whom both sexual organs are equally developed, one who is therefore capable of self-impregnation—has thus far been observed. It is usually difficult to state whether testes or ovaries are present, for these organs are as a rule but rudimentarily developed. Such persons are therefore of the neuter gender. The individual is to be classed with the female sex if uterus and vagina be present, even though there may exist at the same time a large erectile clitoris, very similar to a penis. One case demonstrated was notable, inasmuch as the individual was able to have sexual intercourse with persons of either sex, for the vagina was sufficiently developed to receive the virile member, and the clitoris had attained the size of a penis, but had no orifice.

v. Bergmann showed two patients with bullets in their brains. They proved very interesting cases, for in both the wounds were healed and the patients presented very few symptoms at the time of demonstration. It was quite different though at first. Then there were dangerous features present. In one case, for example, there were at first hemiplegia, hemianæsthesia, one-side deafness, and total blindness. These all passed away, leaving finally a slight paralysis only of the left leg. The projectiles were photographed with the *x*-rays. Notwithstanding the urgent wishes of both patients to have the bullets extracted, v. Bergmann refused to do so, as there was no indication for such interference. Other authorities recommend the extraction of any bullet which can be gotten at, in order to avoid later dangers.

Before the same society a specimen was shown by Dr. Benda, which may serve to explain the origin of general miliary tuberculosis. It was from a case of tuberculosis of the thoracic duct. Of late, the theory of Weigert, that miliary tuberculosis was occasioned by the bacilli penetrating the walls of veins or of the thoracic duct and thus entering the general blood or lymph circulation, has been doubted and attacked. One argument advanced was that the number of bacilli in such a case could not be sufficient to explain a general miliary tuberculosis, and we should have to admit a subsequent increase while in the circulating blood. The specimens shown by Benda of tuberculosis of the thoracic duct and of the aortic and mitral valves presented such enormous amounts of bacilli as fully to account for the general miliary tuberculosis of the respective cases. As a consequence of his investigations and conclusions, Benda fully accepts Weigert's explanation.

Some interesting statistics on the heredity of disturbances of the speech function were recently furnished by Dr. Gutzmann to the Verein für innere Medicin. In all he examined twenty-two hundred and twenty-eight cases of functional and organic disturbances of speech. Of the deaf-mutes there was in but seventeen per cent. of cases a history of heredity; here, therefore, this factor plays but a small part. But 4.6 per cent. of the children of deaf-mute parents (both father and mother) were also deaf-mutes, and in cases in which either the father or the mother was a deaf-mute but six per cent. of the children were similarly afflicted. He also found very few afflicted children whose parents were blood related. Gutzmann added that higher figures are found in America; there more than one-half of congenital deaf-mutes show hereditary predisposition. Patients with functional disturbance of speech, *e.g.*, stuttering and stammering, present a much greater hereditary predisposition.

Vacation begins next month and work in the medical societies of Berlin will be somewhat interrupted. Attention to and attendance upon medical congresses will occupy the time and thoughts of the physician. March and April bring us a number of these medical gatherings. To mention a few: the balneological at Vienna, the German Congress for Internal Medicine at Wiesbaden, the surgical at Berlin, the International Congress for Hygiene and Demography at Madrid, etc. Physicians from every part of the world will work together, and help to tear down the barriers which nature and mankind have erected between the various nations and races. For this surely is one of the educational purposes of an international congress.

The Woman's Hospital of Baltimore is to have a new wing added to the building, in memory of Dr. H. P. C. Wilson, who died recently.

"A CASE OF PUERPERAL SEPTICÆMIA UNSUCCESSFULLY TREATED BY ANTISTREPTOCOCCUS SERUM."

To the Editor of the Medical Record.

Sir: The Medical Record of February 26th contains an article under the above title, by Dr. Hubert Work, of Pueblo, Col. As a general rule, I do not think it profitable, either for the critic or the criticised, to discuss the report of a single case, especially when that case is reported by such a careful and competent observer as Dr. Work is known to be. And yet it is only by a comparison of notes that we can speedily and conclusively determine the value of a new theory or a new remedy; and inasmuch as both theory and remedy in this case are new, this must serve as my apology for a brief analysis of the case in point. It was one of abortion at about the fourth month and was attended by the patient herself, with probably such assistance as could be rendered by a kind and loving husband. The fœtus was expelled on September 9th and the placenta on September 18th, when Dr. Work was first called. For financial reasons the doctor was requested not to call again unless summoned. At his next visit, which was on the 27th, he "found the patient with a temperature of 105° F., a pulse of 120, and the other typical symptoms of puerperal infection." As to his general management of the case, nothing need be said except to indorse it. What I wish to criticise is the misleading title of his paper and his delayed and sparing use of the serum —if, indeed, it was a proper case for the serum treatment. It would have been more appropriate to say "unsuccessfully treated" by curettage, or by quinine and alcohol, as all of these agencies had been used several days previous to the employment of the serum. Dr. Work says very truly that the patient presented the "typical symptoms of puerperal infection." But was it streptococcal infection? He does not tell us whether or not he made a bacteriological test—the only possible means of determining whether the serum treatment was at all indicated. The literature upon streptococcal infection and its treatment is exceedingly scarce, and therefore but few general practitioners have the facilities for giving the subject careful study. For this reason I may be pardoned for quoting briefly from a paper I presented to the section on materia medica, pharmacy, and therapeutics, at the forty-eighth annual meeting of the American Medical Association, Philadelphia, Pa., June 1–4, 1897, and published in the *Journal of the American Medical Association*, September 11, 1897, as follows: "In order that I may not be misquoted or misunderstood, I wish distinctly to state that the antistreptococcus serum is recommended only for streptococcal infection, and not for diseases or conditions in which this infection does not exist. Some cases of puerperal septicæmia are caused by the bacillus coli communis, and in the treatment of these the serum would be without effect. But in the greater number of cases chains of streptococci are found in large numbers, and these yield to the serum treatment in a most remarkable manner. Hence I emphasize the necessity of a bacteriologic examination in every suspected or doubtful case, in order that the treatment may be pursued upon rational and scientific lines."

Assuming even that the doctor made the diagnosis in accordance with the above-named method, his employment of the serum so late in the course of the disease was wholly inadequate. I quote again from the same paper, under the head of "Dosage": "In all grave cases, such as puerperal septicæmia, and especially if treatment has been considerably delayed, an initial dose of thirty cubic centimetres is advised. This may be followed by doses of ten or twenty cubic centimetres every twelve or twenty-four hours, according as the symptoms are affected."

From Paris, where Marmorek's serum is made and used most extensively, we have accounts of as much as ninety cubic centimetres being used within twenty-four hours. This serum being absolutely pure and free from antiseptic substances, the dose is practically unlimited, and no fears need be had in its administration in large quantities. It is not every case of streptococcal infection, however, even of the puerperal type, that requires very large doses of serum, as the one reported by Dr. Siff (Medical Record, November 13, 1897) clearly proves. This case was seen and treated with the serum six days after a normal labor at term, with immediate expulsion of the secundines; while Dr. Work's case carries the history of a placenta retained for nine days, and then only partially expelled, followed by "a little fever" (105° to 106° F.), and the serum treatment not resorted to till two weeks after the expulsion of the placenta, or twenty-three days after the delivery of the fœtus. The two cases are not parallel. One was an acute affection, promptly treated and as promptly yielding; the other at least subacute and saturated with ptomains before the physician was called. In view of the numerous reported cases of this class in which Marmorek's serum was used with signal success, and considering all the conditions attending the one reported by Dr. Work, it seems to me to be decidedly unfair that it should go on record as one "unsuccessfully treated by antistreptococcus serum."

"CASTRATION AS PUNISHMENT FOR RAPE."

To the Editor of the Medical Record.

Sir: I am surprised at the somewhat feeble objections you make in your editorial of March 5th to castration as a punishment for rape. Surely to resort at the end of the nineteenth century to the nameless mutilation of a human being as a punishment for crime would be to step back into the semibarbarism of the middle ages. That sort of treatment would not be in harmony with science, civilization, or Christianity—three terms that are nearly synonymous. Most criminals can be included in the following definition: A human being who, on account of heredity, environment, cerebral deficiency, or disease, is different from and dangerous to normal human beings. If this is true, how shall we treat these abnormal humans? The law of God and man forbids vengeance. The law claims to administer "punishment," not as a penalty for crime, but to deter others from crime. Does it accomplish this? I think all students of sociology will support me when I answer with a most emphatic negative. The mind of the criminal is one that cannot be reached in that way. Most crimes are committed with a full knowledge of the legal penalty, and in many cases the criminal knows that there is hardly a possibility of his escaping that penalty, and in some cases he makes no effort to do so. Does the penalty deter in these cases? In the case of rape the penalty of castration will not only not deter, but will not prevent a repetition of substantially the same crime by the same criminal. On the other hand, a great mass of evidence goes to prove that castration makes the criminal even worse and more dangerous to his fellowmen than he was before. The legal treatment of criminals should tend to elevate them, not to debase them still farther. The penitentiary or State prison should be a combined hospital and school, where these unfortunate creatures can be elevated and improved morally, mentally, and physically, until in the opinion of

experts they are able to associate with their fellowmen with comfort to themselves and safety to others. These institutions should be under the direction of men expert in the treatment of such conditions of mind and body as result in crime. For the community to wreak vengeance on the criminal is simply to make the community criminal. The community gets the best of it only because it is stronger than the individual. The motive that punishes crime is as criminal as the motive that inspires crime. The criminal should be confined for the protection of the community, and advantage should be taken of that confinement to make of him a normal man if possible. In the cases in which this is not possible, he should simply be kept in confinement under the best possible conditions for his improvement.

Mill Burn, N. J., March 5, 1898.

ABDOMINAL HYSTERECTOMY FOR ACUTE PUERPERAL SEPSIS—A REPLY TO DR. BOLDT.

To the Editor of the Medical Record.

Sir: I desire to state at the outset that what follows must not be taken as an implied criticism of the report published in the Medical Record of March 12th, of the discussion on my second case of abdominal hysterectomy for acute puerperal sepsis. I fully understand that your space does not permit the publication of the discussion in full, and I have only the highest praise for the accuracy and fairness of your reports in general. But in the interest of science and of justice, and in nullification of Dr. Boldt's criticisms, some features of the case that were omitted from the Record's report, and also from my report, should be made known to the profession. The woman was in her fortieth year; was a primipara, had a contracted pelvis, necessitating high forceps (applied by physicians from the New York Lying-in Hosiptal) and such severe traction that a dead child was obtained. The cervix was torn deeply beyond the vaginal junction. Would such a uterus, therefore, in a woman of that age, with a deformed pelvis, call for any consideration in a life-saving procedure? What chances would the woman have of again conceiving and having a successful issue, assuming that her life could have been saved by an operative procedure other than removal of the uterus? My critic must grant that the woman had peritonitis, as evidenced before operation by the dry coated tongue, the rapid and intermittent pulse (130), by the temperature (103° F.), by the distended and sensitive abdomen, and by the respirations (46).

At the time of operation there were incontrovertible evidences that peritonitis of a grave nature was present. There was grayish, turbid fluid in the peritoneal cavity, the intestines were very much distended, and the peritoneum had a dirty, opaque, grayish appearance, such as is seen in a rapidly fatal septic peritonitis following a laparotomy. Had the woman been young and the retention of the uterus and adnexa been a matter of vital importance, the question would be pertinent whether the result would have been the same had the peritoneal cavity been merely irrigated and drained and the uterus and its adnexa left *in situ*. I confess now, as I did in the discussion, that a positive answer cannot be given, as I know of no data upon which to form an opinion. My train of reasoning was briefly as follows: the tear in the perineum and cervix was covered with healthy granulations; there was no exudate or evidence of a diseased tube or ovary; hence the source of infection must be within the uterine cavity. I have since learned from the physician who applied the forceps and delivered her that after the child was extracted there was a rush of air from the uterine cavity. The same phenomenon occurred two days later when the iodoform gauze that had been used to pack the uterus was removed. This was so striking that an examination was made for the aerogenes capsulatus, with negative result. I curette the uterus and remove considerable decidual tissue and débris. There is marked improvement for about twenty-four hours; then the patient rapidly grows worse in spite of repeated intra-uterine irrigations, the pulse becomes very weak and intermittent, the respiration more rapid, and the abdomen grows enormously distended. In my opinion, based upon several experiences in such cases, the fatal termination is not far off. I decide to give the woman one chance out of a hundred, by opening the abdomen and flushing it with saline solution, and to extirpate the uterus, for the purpose both of favoring drainage and of removing the gross source of infection. The result is marvellous. On the next morning, twelve hours after the operation, the pulse is regular and full (96) and the temperature is 100° F. The woman makes a good recovery and is able to leave the hospital at the end of four weeks, and is now, ten weeks after operation, fat and rosy looking.

Dr. Boldt said: "It was not a case of acute puerperal sepsis, for if such had been the case the woman would have been dead before the time mentioned [the nineteenth day] as that at which she had first come under observation." At the February meeting of the Harlem Medical Association, when I presented the specimen from my case, Dr. Van Santvoord presented the uterus of a case of puerperal sepsis that had been under his observation at the Manhattan Hospital. The woman died, I believe, on the twentieth day after confinement. The uterus presented very nearly the same characters as that in my case, excepting that it was soft and flabby, having been fresh while my specimen was hardened in alcohol. There was no purulent collection anywhere.

In October of last year I saw a case of puerperal sepsis (with no pus collection or exudate); the patient had been delivered on September 28th, and died October 14th, the eighteenth day of the puerperium. I can recall other cases seen in consultation during the past few years that ended fatally as late as the third, fourth, fifth, or sixth week. It may be that the term "acute" should not have been applied to these cases; but they were acute enough in their severity to kill.

I should not have trespassed upon your space and upon the indulgence of your readers to such an extent, were I not keenly alive to the responsibility assumed in advocating hysterectomy for acute puerperal sepsis. I am anxious, therefore, that my position should be fully understood. In the large number of cases I have seen, and am constantly seeing, I have advised the operation in only the two cases reported. As far as it lies in my power I spread the teaching which guides me in my practice—that by far the greater majority of cases of puerperal sepsis can be successfully combated by proper palliative measures, and that only very rarely do we meet with a case in which the question of hysterectomy ought to be entertained. Even in these cases less serious measures, such as curettage and intra-uterine douching, should first be tried.

Despite the age of Semmelweiss' theory, it would appear we still seem not to have grasped fully the idea that puerperal sepsis always has a local origin, and that it should be treated upon surgical principles, as one would an infected wound elsewhere. If the infection is making headway in spite of our efforts, and if the source is so situated that it can be removed, then we must set to work to do so, as we would with

an infected appendix that is threatening or causing a general septic peritonitis.

In these tragical cases, for I can conceive nothing more truly tragical than when a young primipara is taken away from her newly born babe and from her husband, or when a multipara is taken away from a number of young children, we ought not to split hairs but rather join hands in an effort to save life.

HIRAM N. VINEBERG, M.D.

THE VALUE OF NITZE'S ELECTRIC CYSTOSCOPE IN THE DIAGNOSIS OF HYPERTROPHY OF THE PROSTATE GLAND—A REPLY TO DR. E. FULLER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with a great deal of interest Dr. Eugene Fuller's remarks on "Cystoscopy in Connection with Prostatic Hypertrophy—A Reply to Dr. W. Meyer," in your issue of March 12, 1898. His presentation of the question affords me an opportunity to state—I can only say "again"—what the cystoscope *can* do in determining or rather substantiating the diagnosis, hypertrophy of the prostate.

Dr. Fuller commences his reply by saying that I made a misstatement regarding him when writing in my article on "Bottini's Galvano-Caustic Radical Treatment for Hypertrophy of the Prostate," which appeared in your issue of March 5, 1898, that he had maintained at one of the late meetings of the section on genito-urinary surgery of the academy that this (the diagnosis of the configuration of the prostate with the help of the cystoscope) was an impossibility and mainly existed in the phantasy of the observer. He quotes himself as having said that "great reliance could not be placed on the cystoscope in definitely determining just what constituted the obstruction to urine drainage in cases of prostatic hypertrophy, and that this was due to the fact that only such obstructions could be seen by the aid of the instrument as encroached on the vesical cavity or were what are called intravesical hypertrophies;" also that "no one with a vivid imagination should attempt to diagnosticate prostatic obstruction from what he thought he saw through the cystoscope."

It is true, I was not present at the meeting in question. A friend had informed me of these remarks of Dr. Fuller. But, it seems to me, there is very little difference in the meaning of the words as Dr. Fuller puts them himself and as I put them in my article. However, if my version of his former declarations as given in my article was really a misstatement at that time, it is so no longer, for Dr. Fuller continues in his reply: "In many cases of prostatic hypertrophy the obstruction is caused by growths about the prostatic urethra and about the vesical neck, regarding the presence of which the cystoscope does not give us the least information."

I must confess I was more than astonished to read how little faith Dr. Fuller has in the value of cystoscopy as far as the diagnosis of the hypertrophied prostate is concerned.

In order to show what an amount of positive information the cystoscope gives us in cases of prostatic hypertrophy, when the obstruction is caused by growths about the prostatic urethra and about the vesical neck, I beg that you let me briefly review the method employed in making a cystoscopic examination of the bladder in a patient afflicted with a swollen prostate.

After proper preparation the cystoscope is introduced. The beak approaches the prostatic urethra. We have to press the handle down a great deal before the beak slips into the viscus, a sure clinical symptom that the gland is enlarged. This characteristic, of course, the cystoscope has in common in such cases with all other solid instruments. Then the light is turned on and the instrument drawn out so far that the prism just enters the bladder. What do we see at this spot in the normal bladder? A sharply cut half-moon of a reddish-gray color, its concavity pointing upward. It represents the diaphanoscopic picture of the so-called "inner fold" of mucous membrane around the upper circumference of the internal orifice of the urethra. On account of the peculiarities of the optic apparatus this picture is seen inverted, and is, therefore, observed in the lower half of the cystoscopic picture. What do we see at this spot in cases of hypertrophy of the prostate? A distinct groove, shallower or deeper according to the size of the gland. In 1889 Max Nitze, of Berlin, in his text-book on cystoscopy (Wiesbaden, J. F. Bergmann, page 223), dwelt at length on the great value of this phenomenon in the cystoscopic diagnosis of prostatic hypertrophy. In 1893, after five years' experience with cystoscopy, I could corroborate Nitze's statement in every particular. I then said in my article "On Cystoscopy," in the "System of Genito-Urinary Diseases, Syphilology, and Dermatology," edited by P. A. Morrow, M.D., of New York, vol. i., page 477: "Very important for diagnosing hypertrophy of the prostate is the (diaphanoscopic) picture of the fold of mucous membrane around the upper circumference of the internal orifice of the urethra, to be briefly called 'inner fold.' . . . If the prostate is in the state of hypertrophy, this neatly and everywhere equally outlined thin fold is thickened, irregular, and nodulous. The gentle concave curve is represented by a deep angular notch with two upwardly divergent thick folds."

These statements still hold good. After ten years of extensive cystoscopic work, I repeat to-day, there is not to my knowledge a better pathognomonic symptom for the presence of hypertrophy of the prostate, than this angular notch in the cystoscopic picture of the inner fold. It has never proven fallacious in all my experience; it is absolutely characteristic and reliable for this and for no other intravesical trouble. This, of course, does not imply that hypertrophy of the prostate cannot exist without the presence of this endoscopically observed groove of the inner fold, although I am convinced that cases in which it is not found will be rare exceptions. The important point is rather this: when we do see the angular notch, we can be sure of prostatic enlargement.

If rectal digital palpation, if exploration of the bladder with a stone searcher fail to show a beginning enlargement of the prostate, the cystoscope can do this on the basis of this phenomenon. "There are no means at our disposal to give us equally sufficient and reliable information regarding a pathologic change about the vesical neck, other than the exploration of the bladder with cystoscope No. 1" (Nitze).

But can we not view the enlarged prostate directly, illuminated by the electric light? Of course, we can do this. Let the one who is interested in this matter take Nitze's cystoscope No. 2, with the lamp at the convex side of the beak, and let him inspect the enlarged gland through the optic apparatus (Morrow's "System," vol. i., pages 441 and 442), and he will unmistakably see both hypertrophied lateral lobes in the most brilliant illumination. And if there be a middle lobe besides he will be fully able to distinguish all the three lobes, and on their surface the reflex of the small incandescent lamp which has produced this prostatic revelation. Emil Burckhardt, of endoscopic fame, gives two beautiful illustrations of the hypertrophied prostate as seen through cystoscope No. 2, in his "Atlas der Cystoskopie," plate viii., Figs. 18 and

20 (Bâle, 1891, Benno Schwabe). On account of their clearness and importance as to the value of the electric cystoscope in the diagnosis of prostatic enlargement, I had them reproduced in the above-mentioned article of mine in Morrow's "System," page 491, Figs. 29 and 30. Burckhardt particularly says in the preface to his "Atlas": "All the illustrations have been sketched by myself during the endoscopic examinations. They represent the conditions as they were really seen. No alterations whatever have been added to improve the clearness of the pictures or to facilitate their interpretation."

He who absolutely wishes to see yet more of the prostate by direct inspection may buy Nitze's cystoscope No. 3, with the beak in position rectangular to the shaft (Morrow's "System," *l. c.*). If, after he has succeeded in entering the bladder and pushing the beak into the viscus about one inch, he will slowly turn the instrument around its longitudinal axis, he will find that he can view the immediate circumference of the vesical neck in its natural size. After the beak has returned to its original position he will have inspected a circle the size of a silver dollar, the centre of which is represented by the internal urethral opening.

But let us return to the capabilities of Nitze's electric cystoscope No. 1, the cystoscope *par excellence*, as far as prostatic hypertrophy is concerned. After having definitely diagnosed the beginning or advanced enlargement of the gland by the characteristic cystoscopic picture of the internal fold, we push the instrument farther into the brightly illuminated bladder. Does the latter furnish symptoms absolutely and only characteristic of hypertrophy of the prostate? Yes, it does. We see the trabecular bladder with or without diverticula, in most instances an unmistakably clear, a most beautiful picture. One glance suffices to make the diagnosis; and, if made, it means mechanical obstruction to the outflow of the urine. This again, in ninety-nine out of a hundred cases, points toward the presence of hypertrophy of the prostate, the only other condition that might come into consideration being tumor of the prostate. Of course, in cases of stricture of the urethra a trabecular bladder is also observed if cystoscopy is performed right after stretching a stricture of long standing. However, a mistake as to a correct interpretation is excluded, because in these cases the cystoscope of No. 21 or No. 24 French gauge could not have been introduced.

We furthermore very often see at the border line between the vesical fundus and the internal urethral orifice a nodulous mass, projecting more or less into the cavity of the bladder. A little farther back we then look down into the postprostatic pouch. In estimating the real size of this mass we must remember the peculiarities, especially the magnifying power, of the optic apparatus of the cystoscope. The mass projecting between prism and lamp is of a bright red color, on account of the oblique direction of the rays of the lamp.

That we can thus by means of the cystoscope well diagnose a general hypertrophy of the prostate gland, also in cases in which we have seen an enlarged median lobe, is evident. I can assure Dr. Fuller that I also did this when I cystoscoped the gentleman on whom Dr. Keyes later performed suprapubic radical extirpation. I can further assure Dr. Fuller that I have not been purposely "careful"—as he puts it—not to mention that I did find out a general hypertrophy of the prostate with the help of the cystoscope. But in the case mentioned the question to be determined by the cystoscope was: Has the patient (a prostatic for many years) a median lobe or not.

I wish here to emphasize the fact that for the last ten years I have in all my writings on cystoscopy always insisted upon cystoscopy being the last resort in our attempts to diagnosticate vesical or renal disease. We should always first exhaust all other means at our disposal properly to classify and define a given case. But if a colleague were to come to me to-day and say: "I cannot find any clinical symptoms in this case which would justify me in diagnosing hypertrophy of the prostate; please look into the bladder with your cystoscope and tell me whether there is such a condition present or not," I maintain that, having in such a case used the cystoscope alone and no other mode of examination, I would give him an answer regarding the configuration of the prostate that would be found correct at a future operation or post-mortem examination.

When I said in my article on Bottini's operation that "we can very well diagnose the configuration of the prostate with the help of the cystoscope," I meant, of course—and I fancy every reader will have properly understood me—that we can diagnose with the cystoscope whether the prostate is hypertrophied or not; if so, whether this hypertrophy is a pronounced or a slight one; whether there is a third lobe or not. These are the questions at issue. An answer to these points is what we need for our clinical purposes. Dr. Fuller's subsequent remarks, as above quoted, prove that he too has thus properly interpreted the word "configuration." To make clay models at the time of examination and have them later on verified by operation or post-mortem examination would, therefore, be a superfluous undertaking. When E. Hurry Fenwick, of London, in his work, "The Electric Illumination of the Bladder and Urethra," proposed ten years ago this procedure in cases of tumor of the bladder, he did so mainly with a view of obtaining a very valuable addition to the clinical history of the case, an addition which can be preserved forever. Such clay modelling would be of service in training one's eye to estimate properly what had been seen within the bladder, in that it would enable one to compare the picture observed at the time of the examination with that obtained at a future autopsy *in vivo seu mortuo*.

Now, still a word with reference to Dr. Fuller's case, which he cites in full, because his experience with this one case induced him to make the statement repeatedly referred to: "No one with a vivid imagination should attempt to diagnosticate prostatic obstruction from what he thought he saw through the cystoscope." What are the facts on which he bases this statement, which, coming from his lips, will naturally have weight with the medical profession? Dr. Fuller has opened a patient's bladder and did not find prostatic obstruction or a hypertrophied median lobe, although such had been diagnosed in this case with the cystoscope by another man. Why, may I be permitted to ask, did not Dr. Fuller himself introduce the cystoscope into this patient's bladder? Why did he rely upon the cystoscopic diagnosis of another man? A specialist like Dr. Fuller, with his knowledge and experience, would certainly have been able either to corroborate or to disprove the cystoscopic diagnosis previously made; and if he had done this he might have spared his patient the suprapubic operation. Cystoscopy was feasible at that time, for Dr. Fuller specially states: "The malignancy had not in the least at that time invaded the lower portion of the bladder." The capacity of the bladder also was sufficient to admit of a thorough cystoscopic examination. Dr. Fuller says that he had drawn off "five or six ounces of urine." There was no ulcerative vesical neoplasm, that means no vesical hematuria, which might have rendered impossible a satisfactory intravesical inspection. Certainly the case Dr. Fuller cites does not prove anything whatever for or against the matter at issue. It simply and only proves that the doctor who cystoscoped the patient, who later on came under Dr. Ful-

ler's care, had made a mistake in his cystoscopic diagnosis, had wrongly analyzed what he had seen by direct inspection. Of course, if one with a vivid imagination thinks he has seen through the cystoscope something in the bladder which is not there, Dr. Fuller is right. But why should just vivid imagination have caused this mistake? Do not our oculists, laryngologists, otologists, etc., sometimes err in interpreting a picture which they have seen through the ophthalmoscope, the laryngoscope, the otoscope? Why should a cystoscopist not make a mistake? Cystoscopy in its present stage is scarcely eleven years old. The eminent cystoscopist of this city whom Dr. Fuller has reference to, probably practised this interesting branch of our science for, say, eight or ten years. Why should he be infallible? I for my part can conscientiously state that whenever I have verified my clinical diagnosis of hypertrophy of the prostate, as made by means of the old standard ways of examination—I say, whenever I have verified this diagnosis with the help of the cystoscope, whenever I did see a median lobe, besides satisfying myself, also with the help of the cystoscope, as to the presence of a general enlargement of the gland, suprapubic incision, whenever such was made, has confirmed the correctness of my former findings.

Mr. Editor, the above statements with reference to the value and to the capabilities of the electric cystoscope in diagnosing hypertrophy of the prostate are not the creations of a vivid imagination; they are the result of a decade's enthusiastic but objectively conducted cystoscopic work.

I know that as to the correctness of these statements I shall be borne out by the cystoscopists of the world.

New York, March 18, 1898. Willy Meyer, M.D.

DR. NORTHRUP AND THE CLEAVELAND CASE.

To the Editor of the Medical Record.

Sir: Allow me to avail myself of your columns to state my connection with this unfortunate medico-legal affair concerning Dr. Cleaveland. First, as to my connection with the affair at all. A personal friend called at my office, bringing an assistant district attorney and Mrs. Carhart with him. After the attorney had stated his wishes, my first words were: "Am I wanted as an expert witness?" His answer was: "Yes." I then said: "An expert witness has the right to decline, has he not?" He said: "Yes; but in the interests of humanity I hope that you will not." I replied: "I do decline, and on no account will I have anything to do with it." To everything he had to urge, I reiterated my refusal with absolute positiveness. After this the mother narrated the case at the suggestion of my personal friend, without giving either names of persons or localities, and asked my opinion upon it. Let it be remembered that until I saw the account in the newspaper I did not know the name of the doctor or whether he lived in New York or New England. Having declined to serve and supposing that what I now said was merely of a private nature, I expressed myself, as nearly as I can remember, as follows: "As the facts are represented to me, my first impressions are that there is some causal relation between the size of the dose and some of the symptoms." I have no remembrance of using any such flamboyant expression as has been attributed to me by the press. To my surprise and annoyance, a few days later I was summoned before the grand jury. The substance of my testimony there was that I had no experience that would enable me to give any answer to the question whether the dose mentioned was dangerous.

W. P. Northrup, M.D.

The Anatomy and Surgery of the Chinese.—Dr. J. J. Matignon (*Archives Cliniques de Bordeaux*, November, 1897), after three years' sojourn in Pekin, says that a study of Chinese medicine convinces one that China is the paradise of routine. The medicine of the Chinese is less advanced, less intelligent, and less scientific than that of Hippocrates. Medical literature is rich; there are volumes remarkable for their size as well as for their number, but they are entirely lacking in originality. They are simply commentaries on the old masters who were contemporaneous with Machaon and Podaliere, who cared for the wounded after the Trojan war. All races, even savages, get some notion of medicine from the experiences of previous generations and the observations of morbid phenomena, but the Chinese are no further advanced than the most primitive people. They are superficial observers, and have made medicine a speculative science, without the solid basis of observation of vital processes. The object of most authors has been to give their theories a mysteriously obscure character, for the Chinese think that the more shadowy and more incomprehensible the idea the more it is worthy of admiration. The Chinese physician never makes any dissections, all that he knows of anatomy is learned from charts more or less fantastically produced, in which nerves, tendons, veins, and arteries are confounded. The head is a solid bone. Between the arm and the forearm there is a kind of patella. The small intestines communicate with the heart. The colon, which has six circumvolutions, opens into the lungs. They have very peculiar ideas in regard to the functions of the heart, brain, kidney, and liver. The heart is the ruler of the body. Ideas of pleasure have their origin in the pit of the stomach. The soul has its seat in the liver, and from this organ emanate noble and generous sentiments. The gall bladder is the receptacle of courage, and the subject is timid or warlike according to its seat. They find sixty-four kinds of pulse in the same subject at the same time. They do not know that the veins have valves. Their histological notions are as follows: The body is composed of five elements—fire, water, metal, wood, and earth—which are in exact harmony with five plants, five tastes, five colors, five metals, and five solid viscera. Disease results from a disturbance of this harmony, which no one but a Chinese has yet been able to perceive. Happily for the Chinese, they have a horror of surgery, it is certainly a fortunate thing, so long as their knowledge of anatomy is so limited. Fear of the bistoury is not the result of fear of pain, but of certain notions in regard to filial piety. Any wound of the body is considered an insult to filial piety. The Chinese seldom submit voluntarily to an operation, and when they do they keep the tumors or

members that have been removed with the same pious care that eunuchs preserve their sexual organs in a bottle, so that, being buried with them, they may present themselves intact in the next world. The Chinese physician does not operate, in the modern acceptation of the term. He really limits himself to the opening of an abscess. The chiropodist is much better equipped than the surgeon. All the instruments known number thirty-six. An insufflation tube for medicated powders is much used, especially in diphtheria. It is of iron and about eighteen centimetres in length. Lancing is very popular, and is employed in fractures, constipation, cholera, and ophthalmia. A Chinaman piques himself on the number of lancings that he has undergone. There is, in the Imperial College of Medicine, a manikin of bronze, bearing a very large number of punctures corresponding to the lancing practised on the living subject. At examination time this manikin is covered with paper, and the candidate for a degree is supposed to have sufficient knowledge of the topography of all these orifices to introduce his lance through the paper without the least hesitation into the orifice corresponding to the disease upon which he has been interrogated. Nothing is known of speculums, forceps, or urethral catheters. Massage has been understood by the Chinese since its earliest antiquity. It consists of superficial or profound friction with the hand or a piece of money. In the method called "loung fou," they use hammering of the muscle and the bone by the use of a small wooden mallet.

An Old-Fashioned and Knowing Nurse.—Professor Syme has always had the reputation of possessing an austere, reserved manner, and in the opinion of those who knew him best this impression will be pronounced well founded. At the same time it is no less true that he possessed the faculty of making himself very agreeable to all such as had any claim to his kindly recognition. To the venerable nurses, such as Mrs. Lambert and Mrs. Porter, who served in his wards with the utmost fidelity and industry for half a century or thereabouts, nothing could exceed the kindness and geniality of his manner. When either one of these devoted characters happened to be indisposed, he was always ready and willing to give her his kindest and best care. Whenever an opportunity occurred, he was proud to call out and show forth the surgical intuitions and marvellous diagnostic power of these venerable women, who were not "trained nurses," such as we have to-day, but were educated in the school of experience to a degree which, so far as my observation goes, made them equal in most respects to the best "trained nurses" I have ever known. For example, a young man, pale and emaciated, appeared in the professor's waiting-room one day, with a fluctuating swelling just above his right ankle. After careful examination by all present, various opinions having been expressed as to the diagnosis, the professor, looking around to Mrs. Lambert, said: "Mrs. Lambert, what do you think?" "I think it is a psoas abscess," was her modest but confident response; and so it proved to be, the autopsy a few weeks afterward fully corroborating her diagnosis. Having made the above warm reference to this venerable nurse, who had grown old in the service, I feel justified in adding a few words more in regard to her. In so doing I feel certain that, of all the pupils who studied surgery under Professor Syme during Mrs. Lambert's long service, there does not survive one who will not feel gratified by any kindly or appreciative testimony which may be recorded in her honor. Mrs. Lambert had her own suite of plain but comfortable rooms in the Royal Infirmary. One feature of her housekeeping, upon which she especially prided herself, was her potato soup, or, as she called it in the Edinburgh vernacular, "tattie soup." When any member of Professor Syme's staff happened to be delayed by his duties beyond the regular lunch hour, Mrs. Lambert was ever on the alert with an offer of a plate of this soup, with regard to which she always declared, "It's a wee bit better to-day, sir, than usual." It almost seems that I can taste that "tattie soup" to this day. At all events, the memory of the generous kindness of the good old heart of Mrs. Lambert never has faded and never can fade from my memory.—Dr. Donald Maclean, "Personal Reminiscences of Syme," *Medical Age*, Detroit.

The First Ovariotomy. — Christopher Heath, F.R.C.S., in one of the Lane course of medical lectures, delivered at Cooper Medical College, San Francisco, Cal., September 24, 1897, said: "There can be no question that the first ovariotomist was Ephraim McDowell, who was born in Rockbridge County, Virginia, on March 11, 1771. He went over to England, as was very much the custom with Americans in those days, for there were really no American schools. At Edinburgh he came into relation with Lizirs, who was a surgeon of that city and who had the notion, though he had never carried it out, that it must be possible to remove an ovarian tumor. McDowell came back to the United States and settled down to a small practice in a mere village (Danville, Ky.), and there happened to have a patient come before him in the year 1809, a Mrs. Crawford, who had a large abdominal tumor. The woman had supposed herself, as is often the case, to be pregnant; but when months went on it became clear that it was not a case of pregnancy, and she applied to McDowell for relief. McDowell, entirely on his own authority and apparently without consultation with any one else, performed the first ovariotomy in this country village, and most providentially that patient got perfectly well." In the *Boston Medical and Surgical Journal*, November 5, 1896, page 478, we find the following: "According to 'Memorials of the Faculty of Physicians and Surgeons of Glasgow,' by Alexander Duncan, the first ovariotomy was performed by Mr. Robert Housten, of Glasgow, in 1701, or more than a hundred years before the operation of Ephraim McDowell, of Kentucky, who is generally credited with being the earliest ovariotomist. The account of Housten's operation is quoted by the *Quarterly Medical Journal* from Mr. Duncan's book. It was published in the thirty-third volume of the 'Philosophical Transactions,' London, 1733. Whether the claim that this was the first recorded ovariotomy is true or not, the account is interesting reading."

A Rare Case of Vitiligo.—Dr. Reinhard (*Münchener medicinische Wochenschrift*, June 22, 1897) reports the case of a patient, born of negro parents, aged forty-three. He was in vigorous health and the father of several children. At the age of sixteen years white spots commenced to show themselves on his thighs; later they appeared on his body, and at the age of twenty-five he had become entirely white. At the age of twenty-seven years, after the skin had been entirely white, dark spots appeared on his body which continued to grow darker. In 1894 the patient's surface presented more black spots than white ones. A short time after this black spots formed on his legs and shoulders. His hair was black and curly, while his beard was white. His skin showed no thickening at any part, excluding any idea that the affection might be leprosy. Thus this unfortunate negro, after having become white, then white and black, again became black.

Tumors of the Rectum.—Dr. George Bingham (*Canadian Practitioner*, December, 1897, page 861)

says: "It is to be noted that there are certain characteristics common to the group of benign tumors of the rectum and serving to differentiate them from the malignant growths about to be considered. These features of the benign tumors are: 1, the pedicle: 2, no invasion of the deeper tissues; 3, no tendency to break down *per se;* ulceration or sloughing usually caused by mechanical pressure; 4, no metastasis; 5, a tendency to encapsulation; 6, no constitutional effects; 7, no tendency to return when removed; 8, of the malignant neoplasms of the rectum the one most commonly met with is adeno-carcinoma or malignant adenoma.

Some Causes of Defective Eyesight.—Among the phases of modern scientific methods calling for special study is the depreciated eyesight in the case of sailors, due to the brilliant electric light used on shipboard. Gray and blue eyes, not being heavily charged with pigments, are found to be the most subject to injury. Resort is had, by those working the searchlights, to the wearing of dark blue glasses. These, however, while tending to mitigate the intensity of the light, fail to absorb the source of the trouble—namely, the ultra-violet rays. The latter, nevertheless, can be intercepted by goggles or screens of uranium, or yellow glass, and these, it is expected, will in course of time be extensively introduced. Operators with the electric drill—burning out holes in a hardened steel plate—have sometimes had to be treated for intense pain and partial blindness. This kind of drill, as is known, acts by fusing a hole through the steel, and the intensity of the light is greatly increased by the rays thrown off by the molten metal. The use of dark glasses by those engaged in this kind of work has proved a great boon in obviating its otherwise disastrous effects. A singular feature of the injury done to the eyesight is a remarkable similarity to snow or desert blindness, being, as in these, probably due to the ultra-violet rays of the spectrum.—*Sun.*

Sex and Population.—The *London Post* has lately called attention to the statement that Egypt is said to enjoy the singular distinction of being the one country in the world where men exceed women in number. By the latest census the male sex in the dominions of the Khedive exceeds the female by 160,000. This alleged distinction of Egypt lacks, however, the important feature of being accurate. Egypt is not the only country in which women are outnumbered by men. There are others, several others, and in the number of these are the United States. By the census of 1890 there were in this country 1,513,510 more male than female inhabitants. In Australia the disparity between the sexes is even greater than it is here. Nor can this preponderance of men be ascribed to the comparatively recent settlement of the United States and of Australia, for in Italy men outnumber women and by the last Italian census there was an excess of male over female inhabitants in the proportion of 50.2 to 49.8. Nor is Italy the only European country in which this disparity is to be found. In Greece the percentage of male inhabitants is higher even than it is in Italy, and so it is, too, in Servia and Roumania. In all the South American countries, with the exception of Chili and Venezuela, men outnumber the women, and this is particularly the case in Brazil and the Argentine Republic. In England's South African colonies, in India, in Canada as well as in Egypt, the number of male inhabitants exceeds the number of female inhabitants, and it is not easy, therefore, to see how such an error should have been made as to say Egypt was entitled to the distinction claimed for it, provided always that an excess of male population may be regarded as a distinction. Egypt's claim to any particular prominence in this matter is based on a very slender foundation at best. By the census previous to the last one, it was shown that the total number of male inhabitants was 3,402,000 and the number of female 3,416,000. In a population, therefore, of nearly 7,000,000 the excess of female inhabitants at that time was 14,000, and if since then the scale has been turned slightly, and now shows a small preponderance of men, there is certainly nothing in it which particularly calls for any great demonstration of surprise.—*The Sun.*

Insanity in England.—The secretary of St. Luke's Hospital for Insane in London gives it as his opinion, based on experience gained from many years' contact with lunatics, that the most frequent cause of insanity is overwork, and particularly any prolonged form of labor of a monotonous kind. The following is a classified list of some of those who have been admitted into English asylums during the past five years: 579 agricultural laborers; 484 engineers and artisans; 299 bank, insurance, and other clerks; 214 shopkeepers; 213 soldiers; 176 teachers, etc.; 61 commercial travellers; 44 musicians; 30 doctors; 28 clergymen; 28 authors and journalists; 22 actors.

Medical Etiquette in China.—Chinese doctors are said to be even more scrupulous than their white brother practitioners in regard to the nice points of professional etiquette. Indeed, if report be true, this honorable custom is at times carried to very inconvenient lengths. The following amusing tale is related in an English journal, which, if not veracious, is at least *ben trovato:* "A Chinese gentleman was struck by an arrow, which remained fast in his body. A surgeon was sent for, and broke off the protruding bit of the arrow, leaving the point embedded. He refused to extract it, because the case was clearly one for a physician, the arrow being inside the body."

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended March 19, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Haynesville	March 11th	400	
Mobile	February 5th to March 12th	22	1
Rock Springs	March 11th	15	

SMALL-POX—FOREIGN.

NOTES[1] ON PARASITES, 49: TRUMBULL'S ALLEGED CASE OF "EUSTRONGYLUS GIGAS" PROBABLY A CASE OF FILARIA SANGUINIS HOMINIS.

BY CH. WARDELL STILES, PH.D.,

ZOÖLOGIST, UNITED STATES BUREAU OF ANIMAL INDUSTRY.

IN a recent number of the MEDICAL RECORD there appeared an article by Dr. John Trumbull[2] in which the author gave an account of some worms he found upon microscopic examination of the urine of a patient resident for twenty-two years in Valparaiso. Dr. Trumbull identified the parasites as *Eustrongylus gigas*, and published the case because of the interest attached to finding this rare helminth in man.

In view of the extreme rarity of this species in the human subject, it is necessary to subject to a severe critic every case reported before accepting it as valid, and on this account I may be pardoned for drawing attention to certain statements Trumbull has made which lead me to differ in opinion with him and his consultants, in regard to the correctness of his zoölogical determination.

My objections to admitting this case as one of infestation with *Dioctophyme visceralis* (*Eustrongylus gigas*) are, first, that the description of the parasite, as given by Trumbull, does not apply, either anatomically or biologically, to the Giant Strongyle: second, that it does apply both anatomically and biologically to another worm, namely, *Filaria sanguinis hominis*.

Referring first to the ova which Dr. Trumbull describes and figures. The ova of parasites are very characteristic; so much so that we not only are able to diagnose the presence of worms by finding their eggs, but in many cases we are able to determine the genus and even the species of a parasite without seeing the adult form. The egg (Figs. 10 and 11) of the Giant Strongyle is unusually characteristic, and should not be mistaken for the egg of any other parasite; the structures which Trumbull figures as "ova and débris of shells," are, however, totally unlike the eggs of the Giant Strongyle: in fact, they do not resemble the egg of any nematode, and, although some of his figures bear a distant resemblance to certain trematode eggs, I doubt whether they are really eggs at all: possibly they are degenerate epithelial cells.

Again, while the embryo which Trumbull figures bears a certain resemblance to the embryo of the Giant Strongyle, critical examination shows that it differs from the latter in several important anatomical details. This will appear clear if we compare the following accounts of the embryos which Trumbull describes and embryos which Balbiani raised from eggs of a Giant Strongyle.

According to Balbiani, professor of zoology at the Collège de France, the embryo (Figs. 12 and 13) of the Giant Strongyle measures on an average 240 μ long by 14 μ broad: it is fusiform and terminates distally in a conical tail. The mouth is at the anterior extremity: it is a round opening, and shows no trace of the six papillæ found in the adult; it is armed with a small perforating tooth which the animal extends and retracts at will; the cuticle shows a fine and regular transverse striation. The œsophagus is cylindrical and about one-fifth as long as the body: its anterior portion is broader than the posterior portion, and terminated by a dental armature (*d a.*) formed by three small chitinous pieces which develop at the expense of the inner cuticle.

Trumbull describes the embryo he found as follows: "It had the appearance of a diminutive angleworm, tapering to a point at the posterior end: while at the head there was a much slighter narrowing, which ended in a circular opening. From this opening a fine thread-like process was seen to protrude now and then. Both ends were light in color, and of a faint bluish tint, though a dark line could be traced running from the mouth into the body. At the junction of the more transparent anterior portion with the more opaque portion of the body, which took place a little more than one-fifth of the distance toward the distal extremity, there were two dark spots, which, in a couple of specimens found later on, had a faint, distinctly pinkish tint. . . . The hair-like process from the mouth, seen in the first living specimen, is doubtless the perforating tooth. . . . have been able to distinguish three small papillæ or nodules on the edge of the flattened mouth, and infer that the characteristic six will be found in a more perfect specimen."

In comparing these two descriptions we must recall that Balbiani is a zoölogist and Trumbull a physician; on this account we must naturally expect differences in details. The comparison shows us, however, that Balbiani distinctly asserts that no papillæ are present on the anterior end of the embryos, while Trumbull states that three papillæ were found. Again, Balbiani describes an extremely important organ, the tridentate armature of the anterior portion of the œsophagus, while Trumbull has evidently not found this structure. Here we have two very important anatomical differences between the embryos which Balbiani experimentally raised from the eggs of the Giant Strongyle, and the embryos which Trumbull assumes to belong to this species. It would be perfectly possible for me to assume that Trumbull, not being a zoölogist, would overlook the tridentate armature, but it is difficult for me to believe that so exact a zoölogist as Balbiani would overlook oral papillæ in case they were present: more especially as he evidently searched for them, since he knew their importance as zoological characters.

My next objection to Trumbull's diagnosis is that the embryo of the Giant Strongyle does not develop in man. Balbiani has shown that when laid the egg contains but two blastomeres, and that experimentally in winter it took six months to complete the development of the embryo. While this development might progress much more rapidly in summer, the thickness of the eggshell shows that, in the regular life history of this worm, the egg would in all probability leave the host before segmenting extensively.

[1] Published by permission of Dr. D. E. Salmon, chief of the bureau of animal industry, United States department of agriculture.

[2] "A Case of Eustrongylus Gigas," MEDICAL RECORD, liii., 8, August 21, 1897, pp. 256–258, Figs. 1 and 2.

Trumbull's supposition that the albuminous fluid of the urine furnished nutrition for the developing egg is contrary to the regular order of things among nematodes; in these worms the nutriment for the egg is stored up in the egg itself.

Trumbull's description and figures seem to me to correspond much more closely to embryos of *Filaria sanguinis hominis* than to strongyle embryos. In this filaria embryo we find the "hair-like process from the mouth," mentioned by Trumbull; furthermore, this worm is provided with six oral papillæ; finally, the embryos of this form are found in the urine as well as in the blood.

From Trumbull's description it is impossible for me to determine which particular form of *Filaria sanguinis hominis* (*Filaria Bancrofti*, *F. loa*, *F. perstans*, *F. Demarquayi*, or *F. Magalhaesi*) is infecting his patient, but I would suggest that *F. Magalhaesi* has been recorded from South America.

The Giant Strongyle, which Trumbull thought he had found, is the largest nematode known to occur in man, but it is comparatively rare in this host. It has been known since 1570 (perhaps longer), and has been reported quite a number of times as a parasite of man, but R. Blanchard, who has analyzed the reports carefully, admits only nine cases as authentic. These cases are: Blaes (1674), Ruysch (1737), Josephi (1819), Aubinais (1846), Sheldon (1857), R. Blanchard (1886); also one case each by Metaxa (1833), Sachs Bey and Magueur (1887 88). One of my former assistants, Dr. H. O. Sommer, has recently looked up the records of two alleged cases reported for this country, but he does not consider either of them valid.

The parasite under discussion is a nematode of the family Strongylidae, which also contains *Uncinaria duodenalis* (the cause of miner's anæmia), and a number of other dangerous worms. The most important and constant anatomical character found in members of this family is the copulatory bursa on the posterior end of the male.

The family Strongylidae is divided into several subfamilies; the subfamily *Dioctophyminae* (*Eustrongylinae*), which contains the Giant Strongyle, possesses the following characters:

Diagnosis.—Strongylidae with very large body; polymyaire; bursa of male not divided, thick and without rays; spicule single, testicles double; vulva anterior, uterus single. Type genus, *Dioctophyme*.

This subfamily contains only one genus, namely, *Dioctophyme* or *Eustrongylus*. At present there is a difference of opinion among specialists as to which name should be used. I have maintained for some time past that by the law of priority *Dioctophyme* is the correct name, and Hassall and Ward agree with me in this opinion. European authors on the contrary use the term *Eustrongylus;* Blanchard, the great French authority on nomenclatural questions, though admitting the priority of *Dioctophyme*, does not admit its claim to being considered a properly published generic name, and hence claims that it is not entitled to recognition.

The generic synonymy and generic diagnosis are as follows:

DIOCTOPHYME Collet-Meygret, 1802:

1802. *Dioctophyme* Collet-Meygret, *Journal de Physique, de Chimie, d'Histoire naturelle et des Arts*, lv., pp. 458–464.
1851. *Eustrongylus* Diesing, "Systema Helminthum," ii., p. 325. (*Dioctophyme* renamed.)

Generic Diagnosis.—Large cylindrical nematodes of subfamily *Dioctophyminae* (*Eustrongylinae*); anterior end rounded; mouth small, terminal, surrounded by six projecting papillæ arranged in a circle; polymyaire. Male with complete (not lobed), terminal, thick muscular bursa without rays; one spicule, long and slender. Female with blunt posterior extremity, on which is situated a transverse slit, with more or less crescent form—the anus; vulva anterior, ovary single; oviparous; eggs with hard shell. Type species, *Ascaris visceralis* Gmelin.

The genus contains only one generally recognized species, namely, the Giant Strongyle, although three other species have been placed in it. The synonymy and diagnosis of the Giant Strongyle are as follows:

Dioctophyme visceralis (Gmelin, 1790), Stiles & Hassall, 1896:

(1788.) *Ascaris canis* et *martis* Schrank, Verzeichn ss, 7 and 8. (Reference not verified.)
1790. *Ascaris visceralis* Gmelin, Linné's "Systema Naturæ," 13th ed., i., vi., p. 3,031. (In the dog.)
1790. *Ascaris renalis* Gmelin, Linné's "Systema Naturæ," 13th ed., i., vi., p. 3,032. (In the marten.)
1803. *Fusaria visceralis* (Gmelin, 1790), Zeder, "Anleitung zur Naturgeschichte der Eingeweidewürmer," pp. 114–115.
1803. *Fusaria renalis* (Gmelin, 1790), Zeder, "Anleitung zur Naturgeschichte der Eingeweidewürmer," pp. 116–117.
(1802.) *Strongylus gigas*, Rudolphi, Alber's "Beiträge zur Anatomie und Physiologie der Thiere," i., p. 115. (Reference not verified.)
1802. *Dioctophyme* (as genus) Collet-Meygret, *Journal de Physique, de Chimie, d'Histoire naturelle et des Arts*, lv., pp. 458–464.
1851. *Eustrongylus gigas* (Rudolphi, 1802), Diesing, "Systema Helminthum," ii., pp. 326–328.
1860. *Strongylus renalis* (Gmelin, 1790), Moquin-Tandon, "Éléments de Zoologie médicale," Paris, pp. 329–330.
1886. *Eustrongylus visceralis* (Gmelin, 1890), Railliet, "Éléments de Zoologie médicale et Agriculture," pp. 331–332.
1894. *Dioctophyme gigas* (Rudolphi, 1802), Stiles & Hassall, *Veterinary Magazine*, i. (5), May, p. 343.
1896. *Dioctophyme visceralis* (Gmelin, 1790), Stiles & Hassall, *Veterinary Magazine*, iii. (3), March, pp. 159–160.

Specific Diagnosis.—Nematodes of the genus *Dioctophyme;* body cylindrical, slightly attenuated toward the extremities; 14 cm. to 1 m. long by 4 to 12 mm. broad; color red. Mouth terminal, surrounded by six large papillæ, and several smaller papillæ; one large papilla corresponding to each lateral line, two papillæ lying dorsal and two ventral, the median dorsal and median ventral lines running between each set. The lateral lines are rather prominent, each being beset with a longitudinal row of about one hundred and fifty papillæ. The dorsal and ventral median lines and the four submedian lines are less prominent than the lateral lines.

Male: 14 to 35 cm. long by 4 to 6 mm. wide; tail obtuse, bursa entire, without rays, margin with minute papillæ; spicule long and slender.

Female: 20 cm. to 1 m. long by 4.5 to 12 mm. broad; tail obtuse, slightly curved, with papillæ; anus terminal; vulva 70 to 75 mm. from anterior extremity; uterus and ovary single. Oviparous; eggs ovoid, brownish with hard shell, 68 to 80 μ long by 40 to 43 μ broad.

Hosts.—The Giant Strongyle has thus far been recorded in the following animals: Man (*Homo sapiens*); dog (*Canis familiaris*); wolf [old world] (*Canis lupus*); Azara's dog (*Canis azaræ*); maned wolf (*Canis jubatus*); glutton or wolverene (*Gulo luscus* [*G. arcticus*]); European pine marten (*Mustela martes*); Beech marten (*Mustela foina*); European mink (*Lutreola lutreola* [*Mustela lutreola*]); American mink (*Lutreola vison*

[*Putorius vison*]); European otter (*Lutra vulgaris*); *L. solitaria.*

The adult worms (Figs. 1, 2, 6) are generally found coiled up in the kidney, occurring singly, or two or more together. In some cases they seem to have little or no effect upon their hosts, while in other cases they destroy the tissues of the kidney in which they occur, reducing this organ to a mere capsule. The parasite may become free in the abdominal cavity, or crawl through the ureter into the bladder and from here to the urethra; or it may leave these organs and crawl into the surrounding connective tissue, where it produces an abscess.

Dogs infested with these worms are said to howl night and day, to walk with the body curved to one side, the concave side of the body being the side affected. In some cases the nervous symptoms are such that hydrophobia might be suspected. When the parasite is in the ureter or bladder the urine flows drop by drop.

Life History.—The life cycle of the Giant Strongyle has not yet been demonstrated. We know, however, that the eggs (Fig. 10) when laid, have commenced segmentation; they escape with the urine of the host. Balbiani has shown that in winter they develop an embryo (Figs. 11 13) in about six months; this embryo may remain alive in the egg for five years: if it leaves the eggshell it degenerates in water, but will continue to live in albuminous liquids. If the eggs are dried, the contained embryo dies within a few days.

Balbiani fed these embryos to dogs, in the hope of raising the adult form, but his experiments were negative; on account of this negative experiment it is assumed by zoölogists that the parasite probably runs through a larval stage in some intermediate host. Although this intermediate host is not yet determined, the fish have fallen under suspicion, since certain parasites (Figs. 14–16) described from fish, and bearing the names *Filaria cystica* or *Agamonema cysticum*, appear to be larvæ belonging to the genus *Dioctophyme*. Balbiani's experiments upon fish with the embryos of the Giant Strongyle were, however, negative.

According to Railliet (1893) the Giant Strongyle appears to have a rather extensive geographical range, although he believes it is more common in countries rich in aquatic mollusks and crustaceans. It is rare in France, but relatively common in Italy, and has also been reported in England, Holland, Germany, Russia, Japan, North America, and South America.

In conclusion, the Giant Strongyle has been found in various parts of this country, though its exact distribution is not known to us. Welch and others have found it in Baltimore; several specimens are contained in the Leidy collection of parasites belonging to the University of Pennsylvania, and various members of this bureau have found the parasite in dogs in Washington, D. C.

Washington, October 9, 1897.

ACCOUCHEMENT FORCÉ IN THE LIGHT OF MODERN EXPERIENCE.

By S. MARX, M.D.,

ASSISTANT SURGEON, NEW YORK MATERNITY HOSPITAL; INSTRUCTOR IN OBSTETRICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

On several occasions heretofore I have reported from time to time cases as they have come under my care demanding the operation of accouchement forcé. The recital of these cases took place before the various medical societies of this city. Again, from time to time the ever-increasing numbers of cases formed the basis of three different papers published in the Medical Record, the *New York Obstetrical Journal*, and the *American Journal of Obstetrics*. All this preliminary teaching and writing should be positive proof that my deductions and conclusions were not born of one night's thought, but were the production of much thought and study carried over many a day, until now I am in a position to prove convincingly the utility, worth, and absolute value of the resurrected accouchement forcé, to-day called the "elective accouchement." It has been claimed that I am an enthusiast on this subject and will surely ride this hobby to death. Certainly this cannot be, for I am frank and honest enough to admit that only three years ago, as the records of the Academy of Medicine will show, there was no more bitter opponent of this operation, which I now so laud, than I; and many a hard-fought battle have I waged, especially with my friend Dr. Grandin,[1] to relegate this operation where it belonged, "to innocuous desuetude," for I claimed it was dangerous, brutal, and unscientific.

But the progressive scientific man changes his views and ideas in the presence of convincing words and facts; and thus it was with me. The operation has now been performed well over fifty times, but for the sake of concise numerical classification it was deemed better to report in a series of fifty cases at a time. This will enable me to draw proper deductions from such a relatively large number of operations. To those of my professional friends who are constantly belittling the value of the method and as constantly magnifying its dangers, I would say that when their deductions are based, not upon three or four cases but upon a large series, then and then only am I willing to meet them more than half way in discussing such conclusions, and possibly go back to that day, not three years ago, when I so stubbornly contested its value as a legitimate measure. I am compelled to make such a statement, for there seems to be even to this day an inherent fear in the minds of some, who are otherwise clear and shrewd observers, that the elective manual dilatation of the pregnant uterus is fraught with such danger that the woman, not to mention the unborn fœtus, is destined almost certainly to death. Only a few days ago an even-tempered and careful practitioner asked of me, not how many women recovered but how few, and how many after the operation were left in the deepest fatal shock from hemorrhage, uterine rupture, and what not. Such questions are the veriest rot, based upon a conception of the operation which is biassed from the very beginning, a conception fathered by the writings of those who either know nothing of practical midwifery or whose experience is so very limited that the less

[1] Discussion before the Bellevue Hospital Alumni Association.

they say the better for themselves and for the community at large.

I am through defending the operation, for it needs no defence. Its legitimacy and stability as a modern obstetric measure stand upon a rock-bottom foundation. It is neither my desire nor my wish to praise the operation as one to be universally recommended, for there are women, though rare, in whom the operation cannot be done, on account of pathological conditions in the lower uterine segment. This occurred in Case VII.[1] In cases such as this the deep incision of Dührssen has a legitimate field, certainly a worthy and a timely one. But the beauty and the greatest advantage of manual dilatation lie in the fact that it can be made a strictly elective operation, even as any other operation within the domain of surgery. Thus the patient can be surgically prepared, instruments made ready, assistants summoned to hand, and, what is most important, a time appointed at the most convenient hour for all parties concerned. Compare this state with what takes place at an average obstetric operation. An emergency arises; the consultant is hurriedly summoned, and often as not he is not at home. Crude asepsis and antisepsis, the hurry and bustle of an ill-prepared emergency operation can tend only in one direction—invitation to sepsis or other grave complications; and thus in the attempt to save a woman from one grave condition you lead her an unwilling victim to another.

Another very important factor which tends to increase the success of the procedure is that the hand is the only instrument used in the actual operation. All other instruments might possibly be forgotten or lost, but the hand is always present and ready to do sentiently what is demanded of it, so long as there are brains and not brute force at the end of that most important organ, than which no better instrument has ever been made by man, no matter how delicate or how precise its mechanism or its manufacture. I shall not purposely condemn other instruments for the induction of labor for the mere chance present to magnify the utility of the hand. All other instruments designed for this purpose are uncertain. They are all foreign bodies to be introduced into the uterus, and no matter how skilfully cleaned and prepared they still remain foreign bodies, which must, in order that our end may be gained, be introduced into the cavity of the uterus, and thus sepsis may be invited. And even when they are surgically cleansed and introduced are we not often disappointed when at the end of from twelve to forty-eight hours the uterus still lies quiescent and our patient is no more out of the dangerous condition for which we originally intended to operate, in spite of your one or two catheters introduced or your Barnes' bags supposedly pressed into the uterus, they having quietly slipped out and dilated the vagina most thoroughly? Thus good and sacred time is actually wasted, for every hour counts; nay, every minute, as witness a woman on the verge of an attack of eclampsia.

Again, by other measures the membranes are liable to rupture, especially from the introduction of the bougie, and what is more essential than to preserve the integrity of the membranes and thus take advantage of an easy version, the most frequent form of delivery, in the presence of an intact amniotic sac? In the "elective accouchement," when once the actual operation is begun there is no letting up; the uterus is dilated and the child delivered. The woman is thus at once and immediately, so far as possible, relieved from the danger which is imminently endangering her very existence.

[1] "On the Treatment of Placenta Prævia," American Gynæcological and Obstetrical Journal, November, 1895. Report of case.

In the fifty cases reported below I note only one failure to dilate the cervix. This occurred in Case VII., in which the cervix was so cicatrized from previous lacerations that the hand failed and the cervix was opened with the knife, by doing the deep incisions of Dührssen. This case should not, properly speaking, be classified under this category. But the failures of the hand to accomplish its purpose are as essential to the completeness of this paper as the successes. In critically analyzing the report of the cases of placenta prævia I have to note eight cases: of these four were of the variety called "completely centrally implanted" (the Dührssen incision case excluded). Result: Eight mothers—eight alive; nine children—all born alive and when viable all lived (one mother had twins). Certainly this result is an excellent one, even admitted such a limited number of cases. Even the enthusiastic advocates of the Hicks method of treatment admit a fœtal mortality rate of from fifty per cent. to seventy per cent., not saying anything further as to the maternal mortality. All these cases in order to insure against further loss of blood were, directly the placenta was manually removed, tamponed with gauze. Of the accidents occurring during this operation for this complication may be noted one—a deep laceration of the cervix—which necessitated the introduction of three silkworm-gut sutures. This tear I attribute solely to the rapid delivery I was forced to make. This cannot militate against the value of the operation, for forceps and version might also rupture the cervix; and are we going to reject them (forceps and version) because of such a possibility? Nor should we reject the accouchement forcé for no better reason. In this case the woman was placed on her back; her uterus was artificially prolapsed by bullet forceps and pressure from above; the cervix was delivered through the vulva, and sewed up as readily as though the condition was a lacerated perineum.

The next condition for which the operation was performed was that dread state and awful complication, uræmia, or the eclamptic state. We have records of thirteen cases. Result: Thirteen mothers—twelve alive, one dead; fifteen children—fourteen born alive, and when viable all lived (two mothers had twins, one of them dead ante partum, as certified to by the hand in the uterus and accordingly perforated). These results need not be commented upon, for the facts given speak for themselves. The fatal case, occurring in the wife of a New York physician, was a case of true uræmia; hardly any albumin was present, but there was a progressive diminution of the urea excretion from day to day. Death occurred eighteen hours post partum from an acute pulmonary œdema.

While I have in no single case of the series of fifty here reported attempted to operate against time, yet occasionally a case would arise which would necessitate rapid work, but always I took into consideration consistently the integrity of the maternal tissues. For example, the most noteworthy case (Case XL.), a grave case of eclampsia in a primipara at the end of the eighth month. No labor pains; a cervix present nearly an inch long. Yet within seventeen minutes I had fully dilated the cervix, perforated the first baby, which was dead, turned the second living baby, manually removed the placenta, and tamponed the utero-vaginal tract. She made a beautiful convalescence. And yet another case of complete placenta prævia in a Vpara with an extremely succulent lower uterine zone and a long cervix present. The uterus was dilated, twins were delivered by version, the placenta was removed manually, and the uterus tamponed in a trifle less than seven minutes. Aside from a temporary pyrexia everything went along smoothly. Both these cases were timed by the physicians present. Of the remaining

Case.	Seen by or with	Parity.	Cervix Present or Os Admits.	Indication	Preliminary Tamponade	Method of Delivery.	Condition of Child.	Condition of Mother	Labor Pursued	Remarks.

cases nothing further need be noted, for the table appended gives all necessary information, excepting for three cases which warrant more than passing notice.

Case XIX., one of grave scarlatina. When the patient was practically moribund, labor pains started in. This patient should never have been subjected to an operation, for the result showed the baby to have been dead for some time. It was perforated and the mother died several hours later.

Case XXXVI. This was a remarkable case of true pelvic contraction of irregular type. The woman had had several labors and had lost all the babies. All her labors were ushered in by rupture of the membranes. She was now well in the ninth month, with a large baby presenting at the brim with a mento-posterior face presentation. The true conjugate measured three and three-fourths inches. She had a deep perineal laceration and a marked vesicocele of the size of a fist. I advocated either a symphyseotomy or a Cæsarean section at term, but this was denied me and absolutely refused by the family. Labor at term to my mind meant a larger child, a premature discharge of liquor amnii (according to her previous history), and a more difficult and dangerous labor than

if the attempt was made to operate at once; when, I thought, by dilating the cervix by the hand at once, anticipating the discharge of the waters, doing an elective version in a complete fruit sac, I might possibly get a living child. But what a disappointment! The cervix dilated readily, but the large child, presenting by the extended head, caused that head to be still more extended. After the version up went the hands and the after-coming head was delivered with the greatest difficulty. The result—a child dead. The vesicocele, nipped between the head and the symphysis, caused a large vesico-vaginal fistula. It was the result of this nipping and not an extension of a cervical tear, for the uterus was practically intact. Permanent catheter in the bladder and constant irrigation cured this nasty complication. Beyond this the mother made a good recovery.

The most interesting case of the series is Case XLV. This case shows the very great utility of the operation if no other case does. The patient was a very large flabby woman, with every valve in her heart diseased. She had been seriously ill with a capillary bronchitis. This certainly was not a pleasant combination of factors when her labor set in about term. She had not rested on her back in months. Her breathing was bad, her face cyanotic, becoming deeply so with each pain. Pulse rapid, from 120 to 150, small and irregular. So critical was her condition that I refused to operate until one-twenty-fifth of a grain of nitroglycerin had been pumped under the skin half-hourly for two hours. Under an A. C. E. mixture with constant administration at the same time of oxygen, I delivered her successfully in a very short time. I need only in passing mention that her condition was so desperate that the husband was informed and consent given to the performance of a Cæsarean section in the event of her dying on the table. That night was the first time she could lie flat in bed with comfort. Death occurred some weeks later from the cardiac condition.

Of the fifty cases presented, only in one case did the operation fail. In forty-nine cases the operation *per se* was eminently successful.

Mothers operated upon, 50; failure to dilate, 1; successful operations, 49. Mothers dead, as per table, 2, including one patient moribund from scarlatina ante partum, not including one patient dead after laparotomy (Case XLII.) some time later; mothers recovered, 48, including one dead after laparotomy some time after labor.

Babies, 53, out of 50 mothers; 3 pairs of twins; all born alive when alive ante partum, except one fœtus (Case XXXVI.). All babies lived and were born alive when viable, except as above; babies living, 44; hydatids, 1; babies dead intra partum, 1; all the remainder dead some time ante partum, 8.

Labor present in 18; labor not present in 32.

Preliminary tamponade used in 9 cases; not used in 41.

Cervix present in 34 women.

Os admitted one finger in 8 woman; os admitted two fingers in 8.

Total, 50 cases.

Method of delivering baby: Version, 29; embryotomy perforation, 4; ordinary forceps, 8; Tarnier axis traction, 7; direct breech extraction, 3; spontaneous, 1.

Technique of Operation.—With very little variation the operation as described by me and reported in my first paper[1] is still the one employed. The operation divides itself into two stages—the preparatory and the operative. In any case in which the emergency is great, the preparatory stage can be omitted and the direct operation instituted at once; for example, in placenta prævia cases in which the cervix is soft, mushy, and œdematous, and consequently is most readily dilated. As this preliminary stage has for its object the disappearance of the cervix, it may be properly omitted when that portion has merged into the lower uterine zone, the condition so often found in primiparæ near the end of pregnancy; but when the cervix is present in its entirety and no urgent symptoms arise, the patient, rendered thoroughly clean, is placed on the back, a posterior speculum depresses the perineum, and the lip of the cervix is caught in a bullet forceps and traction made downward. Strips of gauze,[1] the width of two fingers, are carried by means of slender forceps into the cervical canal, slowly and gently, until a resistance is encountered. This being used as a backing-wall, the cervix is tightly tamponed with gauze, the vagina is tamponed in the ordinary way, and the patient is put to bed. This method of tamponing is of the greatest importance. Its object is mechanically to separate the membranes without endangering their integrity. It mechanically softens the cervix and causes its mergence into the lower uterine segment and it provokes decided pains, so that in a short time an os which previously has been tightly closed will readily admit one or two fingers. In all these cases the tampons have caused the patients to complain of intermittent crampy pains, indicative of uterine action. In from five to fifteen hours, depending upon the severity of the pains, the tampon is removed, the patient again rendered surgically clean, an anæsthetic given, and the operative stage commenced. When the emergencies are such as to preclude the possibility of using the preliminary cervical tampon and the cervix is tightly closed, a branched steel dilator is carefully introduced and the cervical canal dilated so as to admit one finger.

The most difficult and trying part of the operation is this initial stage, when the attempt is made in the presence of a complete cervix to cause its disappearance. As soon as one hand is tired or if the operator is exhausted, the other hand or a competent assistant may continue. On more than one occasion it has taken from one-half to three-quarters of an hour to cause the cervix to disappear, *i.e.*, merge into the lower uterine zone. But this once overcome, the rest of the operation, the dilatation of the external os, is simply play work. Brute force is unscientific, reprehensible, and dangerous. The physiology of manual dilatation means nothing more nor less than tiring out the cervical muscle by continuous gentle force, instituted by the fingers or hand as an applied force, even as the spasm of the pudendal muscles is caused to yield by the constant pressure of the advancing head. Deliver the head too rapidly, and you use abnormal and sudden forcible dilatation: your perineum tears in an instant. So is it with the lower uterine zone. Gradual gentle pressure prolonged for some time will overcome the cervical spasm, and it will gently melt away under the constant irresistible force of the fingers.

Now as to the second, the direct operative stage. The os is found very soft and dilatable, sufficiently so to admit readily one or two fingers. I have varied the method somewhat now from what I formerly employed, the variation of operating depending on whether or not the head is firmly engaged and normally so. When the head is firmly engaged, as so often happens in primiparæ, I use the fingers of both hands, one passed by the vagina in front and the other behind, hooking them into the cervix and using power by pulling in opposite directions. The hand is not introduced into the vagina. In other words, the fingers, one of each hand, then two, and possibly three, are introduced antero-posteriorly, pulling the whole lower uterine

[1] Medical Record, February 17, 1894.

[1] Iodoform gauze has caused, in the hands of the writer, poisoning from mere cervical tamponade.

segment downward, at the same time slowly but surely dilating the parts in all directions, the fingers of both hands simulating a vaginal speculum, so that one is operating almost under the guidance of the eye. I have on several occasions demonstrated to physicians present the dilatation by this means, when the os could be readily seen to dilate under this measure. My object in dilating in the above-described manner I consider of value, since by the method next to be described the head must of necessity by the impinging fist be forced above the brim, and thus the relation between a well-engaged head in a normal position and the pelvis is disturbed. Further, the application of the forceps to a head in such a position is simple and the delivery far easier than a version under other conditions when the head is above the brim. After the os is thus dilated I have generally employed an axis-traction forceps, after Tarnier, to complete delivery.

Ordinarily, the following method is employed: The hand being introduced into the vagina, one finger is inserted into the os and continuous pressure exercised until the entire finger enters. This finger is now flexed while still in the uterus and slowly withdrawn at the expense of a lessened resistance on the part of the ring. This flexed finger has a diameter equal to that of two fingers. These are then introduced to their fullest extent, both flexed, and withdrawn at the same time. Thus this manœuvre is continued until the spasm is so far overcome as to allow the passage of the conated hand entirely within the uterus. The hand, then closed, is carefully withdrawn. Thus this is done a number of times in the different diameters of the os and continued until no resistance in any direction is encountered on the part of the lower uterine zone. Now the os is found sufficiently dilated for the passage of any ordinary child. The membranes having been preserved, the hand is carried between the uterus and sac, carefully separating them; one or both feet are grasped, and then the bag of waters is ruptured as high as possible, and a pure internal version is done. The reason for doing an internal version and an immediate extraction is because, the cervix being artificially dilated, retraction is almost certain to occur, unless extraction and delivery are performed at once, and that at a most inopportune time, *i.e.*, when the neck of the baby is passing through the os; the latter has a tendency to retract and often tightly hugs that fœtal part with such force that the delay entailed in again overcoming this spasm may prove lethal to the baby.

THE SURGERY OF TUBERCULOSIS OF THE PERITONEUM.[1]

By PARKER SYMS, M.D.,

NEW YORK.

In a large proportion of cases of tuberculous peritonitis simple laparotomy will produce a permanent cure. In the whole domain of surgery there is no fact more remarkable than the one just stated, and it is peculiar and without analogy.

For many years this phenomenon had been observed in isolated instances, and it was regarded simply as a coincidence, and it is not until lately that simple laparatomy has been recognized and advocated as the proper treatment for this form of tuberculosis.

As far as I am aware, the first English monograph devoted to the subject was written by Van De Warker, of Syracuse, in 1887. In 1890, König wrote an important paper on this subject, reviewing the literature and giving an analyzed tabulation of one hundred and thirty-one cases. About the same time William Osler, of Johns Hopkins University, gave the subject special mention in a paper on tuberculous abdominal tumors. In November, 1890, I read before the New York Surgical Society a paper entitled "The Influence of Laparotomy upon Tuberculosis of the Peritoneum," from which I shall take the liberty of quoting later on.

These were among the earlier contributions devoted to the subject. At the time of my first writing the literature consisted almost entirely of reports of cases in which laparotomy had been performed because of a mistaken diagnosis, or as a means of making a diagnosis, and in which cure had thus been brought about accidentally. Now medical literature is full of reports of cases in which the operation has been done as a recognized means of treatment.

Since this subject has been widely discussed and investigated it has awakened the interest it merits, and, the phenomenon being as yet unexplained, it has resulted in the advancement of a variety of theories as to why simple laparotomy should cure such an extensive and malignant disease. I shall enumerate a few of these.

1. It has been claimed that the good result has been due to the use of chemical disinfectants.

2. The result has been attributed to the use of drainage.

3. Some claim that cure has been produced by the exposure of the abdominal cavity to sunlight and air.

4. That cure depends upon the removal of ascitic fluid, and the thereby altered blood circulation.

5. That by the accidental introduction of bacteria a toxalbumin is produced which is fatal to the tubercle bacilli.

6. That the opening of the abdomen and the operative handling of the organs constitute a traumatism which establishes a fibrinous peritonitis, resulting in the encapsulation of the tubercle bacilli and their arrest.

7. That the cure is owing to the advent of leucocytes, and is the result of phagocytosis.

8. That the mere opening of the abdominal cavity by an incision brings about a physiological change in the peritoneum which in some way makes it cease to be a proper soil for the growth of the tubercle bacilli.

No one of these theories can as yet be demonstrated to be true, and some of them may readily be discarded.

That cure does not depend upon the use of disinfectants is shown by the fact that long series of cases in which no such agents were employed show a slightly higher percentage of cures than does a series of cases in which such agents were used.

That the result is not brought about by the relief of pressure accomplished by the withdrawal of ascitic fluid and the consequent improvement of the blood circulation is shown in cases in which the fluid has been removed by tapping without benefit to the patient, and in which subsequent incision has been followed by cure.

That drainage is not the means of cure is shown by the fact that patients get well without it, and that they do better without it than with it.

The other theories which I have stated can hardly be either proved or disproved, but it should be borne in mind that we have no analogy to this phenomenon in other parts of the body. For instance, one will hardly expect to cure a tuberculous joint disease by exposing it to sunlight and air. In fact, I think that we are forced to the conclusion which Tait arrived at, namely, that the opening of the abdomen produces a change in the physiological character of the peritoneum which makes it able to overcome and destroy the tubercle bacillus; but this is merely begging the question, and I confess that I feel that this subject presents a riddle which is still unsolved.

[1] Read before the New York State Medical Association, October 13, 1897.

When I wrote my paper of 1890 I stated certain conclusions at which I had arrived, and, as my subsequent study and experience have tended to confirm my views as then expressed, I take the liberty of quoting them from that paper. The conclusions as set forth are as follows:

"1. That the danger of the operation is very slight (the death rate being below three per cent.).

"2. That sepsis is not so likely to occur in the peritonæa as in laparotomy on healthy ones, on account of the pathological changes which have taken place in the membrane.

"3. That tuberculous infection of the wound does not occur.

"4. That disinfectants are useless, and that drainage should not be used, as it is likely to result in a permanent sinus.

"5. That in unsuccessful cases the operation at least does no harm. Most of the patients who have died after the operation have succumbed to a general tuberculosis, or to tuberculosis of some other organ.

"6. That established—not advanced—pulmonary tuberculosis is an indication for, and not against, the operation; for the improvement gained enables the patient better to resist the phthisis, and if this latter be but incipient recovery may take place.

"7. That laparotomy is the proper form of treatment for these cases. In some unknown way it exerts a beneficial influence upon the disease, resulting in cure in a large proportion of cases, and marked improvement in nearly all."

To confine myself strictly to my text, as set forth under the title of this paper, I shall say but little except as relates to the treatment of this disease. Pathologically we recognize three varieties of peritoneal tuberculosis, as classified by Aldebert: first, the ascitic; second, the fibrous; third, the ulcerous; or perhaps they may be better expressed as the ascitic, the fibrino-plastic, and the caseous or suppurative. These represent stages of the disease rather than distinct varieties, and are frequently found associated in the same case. When the ascitic and the plastic are combined we often have localized encysted fluid, which may readily be mistaken for cystic tumors. So it is when the ulcerous or caseous form is encapsulated by localized adhesions: the mass can often be felt as a distinct tumor, and the diagnosis may be greatly obscured.

Clinically we may recognize two varieties: first, with ascites, and second, without ascites, *i.e.*, either the fibrous or the ulcerous. The peritonitis which is a part of an acute miliary tuberculosis is not amenable to surgical treatment, and is not considered in this paper.

Treatment.—Feeling assured as I do that laparotomy is the cause of cure in patients who recover, and that the good result is not brought about by topical medication, by irrigation of the cavity, or by drainage, I recommend as simple and as safe a method of operating as possible. I believe that the incision should be large enough to allow satisfactory exploration of the abdominal cavity. When hydrops exists the fluid should be fully evacuated. When there is an encysted mass consisting of fluid or of granulation tissue, it is well to separate the adhesions and carefully sponge out the cavity, provided too much tearing and bleeding will not result; otherwise it is better not to make much manipulation.

It must be borne in mind that in most of the cases reported prior to 1892 cure had resulted from simple exploratory laparotomy. In most of these instances the disease was not recognized until the abdomen was opened, and when its nature was ascertained nothing more was done except to close the abdominal wound, as these cases were considered to be inoperable, and when cure resulted it was a surprise to the operator.

When possible the original focus of the disease should be removed. This will often be the case when the female pelvic organs or the appendix vermiformis is the site.

I am convinced that the more simply and rapidly the entire operation is performed the better will be the result, and I advise against irrigation or attempted medication of the abdominal cavity.

Drainage of the abdomen does nothing favorable for these patients, and it will often result in establishing a permanent fistula; it always delays the healing of the wound, which is a very serious thing for this class of patients. It should not be employed.

The wound should be closed by suture, and convalescence from the operation established as soon as possible.

No plan of treatment of any form of tuberculosis is complete that does not include careful attention to the patient's general condition. As soon as possible these patients should be gotten out of town, and under the best possible hygienic requirements.

Many papers have been published on this subject, and several hundred cases are on record. Statistics as to cure of course vary according to different authors. Some claim cures in as high a ratio as eighty per cent.; some only as much as twenty-four per cent. Analyses of these reports show that the mortality from the operation is below three per cent. Marked improvement occurs in about eighty per cent. of cases, and a permanent cure is effected in about thirty per cent. of all cases operated upon.

The following is a list of some of the important articles on the subject:

A NEW PLASTIC OPERATION FOR THE RELIEF OF DEFORMITY DUE TO DOUBLE HARELIP.[1]

By ROBERT ABBE, M.D.,
NEW YORK,
SURGEON TO ST. LUKE'S AND CANCER HOSPITALS; ASSISTANT ATTENDING SURGEON, ROOSEVELT HOSPITAL.

A lad of twenty-one years recently presented himself for a conspicuous deformity of the lips, the sequel of an operation for double harelip in infancy, consisting

Fig. 1. Fig. 2 Fig.

in an extreme flatness and scantiness of the upper lip, with an enormous pouting and redundance of the lower one. He also had a complete cleft of the hard and soft palates, upon which two attempts had been made in former years to close. He desired this to be

Before Operation.

closed first, which I did, and operation was afterward done upon the lips.

Their inequality was admirably corrected by transplanting the middle portion of the lower lip into the upper, as illustrated in Figs. 1, 2, and 3.

A median vertical incision was made in the upper lip, and the central scar portion excised so as to

After Operation

obtain edges of an excellent quality of skin. The gap thus created was about three-fourths of an inch in width.

A flap taken from the central portion of the lower lip, a little wider than the upper gap, was then made,

Before Operation.

in such a way as to make a hinge upon one side containing the lower branch of the coronary artery on the left, which flap was turned upward so that its lower edge on the chin was placed beneath the columna nasi. The vermilion border was exactly stitched on one side, as shown (Fig 2), and numerous very fine stitches were applied so as to secure apposition around three-fourths of the flap. The lower part of the wound upon the chin was also brought in apposition up to the red portion.

Upon the right side of the mouth the upper half

[1] Read at the meeting of the Practitioners' Society, Friday, December 3, 1897.

and the lower half of the red lip were left free until the inverted flap should have grown in its new position. Retention sutures were made to transfix the upper lip from side to side, and also one was passed from below the left angle of the mouth, crossing obliquely to the right upper lip, below the wing of the nose, thus preventing unconscious dragging upon the flaps. These are not shown in the sketch.

On the twelfth day, the flap having grown perfectly in its new position, its base was very carefully cut

After Operation.

from the lower lip so as to leave an ample portion of the red middle lip, which was turned upward and exactly fitted to the freshened edge of the free half of the lip, as shown in Fig. 3. The lower lip was then refreshed and sutured.

The nutrition of this transplanted flap by its new capillary nourishment was so perfect that in color and texture it seemed to have been always a part of the upper lip. The lines of suture rapidly faded and were quite insignificant. The two lips were afterward in about their normal proportion, and gave the patient perfect satisfaction.

During the twelve days between the operations, nourishment was well sustained by fluid taken through a tube inserted through the nostril.

Appendicitis.—Of the various theories advanced to account for appendicitis, the most probable is that which regards the appendix as a diverticulum which readily allows of the accumulation and stagnation of fæcal matter. This, mingling with the secretion from its mucous membrane and undergoing fermentation and putrefactive change, sets up a catarrhal inflammation, which may be followed by ulceration and perforation or by thickening of its walls, the latter condition being the one most commonly met with in the recurrent form of the disease. The fæcal concretions found in its interior are probably the consequence, not the cause, of the inflammation, being due to inspissation of its contents; but, once formed there, they no doubt tend to excite and keep up the recurrent attacks. Though foreign bodies rarely lodge in the appendix, in one of the cases mentioned after numerous attacks of appendicitis an abscess formed, and at its bottom was found a pin.—Dr. George Heaton, *Lancet*, May, 1897.

MY RECENT WORK IN APPENDICECTOMY.

By A. C. Bernays, A.M., M.D. Heidelberg, M.R.C.S. London,

St. Louis, Mo.,

Life Member of the German Surgical Society, Berlin; Mitglied der Anatomischen Gesellschaft; Professor of Anatomy and Clinical Surgery at the Marion Sims College of Medicine of St. Louis, etc.

May 15, 1896, Dr. Robert E. Wilson became my first assistant. I instructed him to keep an account of my work, with particular reference to my operations for appendicitis and for pus tubes. I felt that in these very common affections I had passed the experimental or rather developmental stage, which every operator must pass through so far as the method and technique are concerned. I had done two hundred and seventy operations for appendicitis, and made one hundred and eighty-five sections for the removal of pus sacs. I had employed many different methods, particularly with regard to the antiseptics that were used, and many different methods of drainage had been tested. After about twenty years of this work I finally arrived at a method of treatment the results of which I will now report, and it has given me a measure of success that I can scarcely hope to excel in future.

Since Dr. Wilson has been with me I have operated in eighty-one cases of appendicitis, and in all but one of these the appendix or its stump was removed. Of this series of cases, seventy-one were done in succession, with an entirely satisfactory result, all patients making a perfect recovery. They were all, with a single exception, acute cases; all suppurative or gangrenous; some complicated by general peritonitis. In that exceptional case there was no pus, the appendix being found in a dense mass of cicatricial tissue, and there was no kind of acute infectious or febrile disturbance. The only indication for the operation was pain, and this symptom was completely relieved by the removal of the offending organ. The patient had passed through an attack of acute appendicitis several years before she came to me. I am so averse to operating upon afebrile patients that I had sent this patient to her home, a distance of over one hundred miles, telling her to put off operative interference for three months, in order to see whether or not her pain would disappear under a *régime* of diet and regular purgation. The pain, however, persisted, and she was finally cured by appendicectomy.

I do not wish to be understood as condemning the operation of appendicectomy during the quiescent stage, but I favor operating in every case during the acute stage and as soon as the diagnosis of appendicitis is made. This must be understood to mean that if a patient has passed through an attack of acute appendicitis without losing his or her life under the expectant treatment, I would not urge an operation until a second attack comes on. It is by no means certain that a second attack will ever come on, but, if it does come on, then I would most strenuously urge an immediate radical operation. Eliminating this one case of non-suppurative appendicectomy, there is left a record of seventy consecutive complete operations without a death.

The seventy-second patient in this series died on the third day after the operation. It was a case of long standing; the patient had been sick in bed for over seven months, was emaciated, had rigors and fever continuously, and had an enormously large doughy tumor, filling more than one-third of the abdominal cavity. It extended to the median line and to four inches above the umbilicus. The patient was brought from southern Illinois upon a stretcher, and was in a very unfavorable condition for an operation. I knew that delay meant certain death, and operated at the Rebekah Hospital about twenty-four hours after he reached the city. The operation was a very tedious

one, and although it was completed, and all the pus cavities between the intestines, under the omentum, in the pelvis, and near the root of the mesentery, as well as a large cavity in the region of the kidney, were thoroughly drained, the patient never rallied and his temperature never became normal before he died. He was so much exhausted by the long pyæmia and sapræmia that he had not enough resistance or antitoxic properties in his tissues to overcome the toxæmia which had existed, and to which was added the shock of a prolonged operation. I am certain that this man could have been saved by an early operation.

Since this death interrupted the series of successful cases there have been nine more, and all of them have ended in recovery. In one of these I was compelled to do an imperfect operation. It is the only one in the entire series of eighty-one cases in which it was in my opinion wise to leave the stump of the appendix. I found such a condition of affairs that I removed only the gangrenous appendix, leaving the stump alone and draining the pus cavity, which reached the vena cava and the vertebral column. The cæcum in this case, instead of lying in the iliac fossa, lay near to the vertebral column, and the appendix arose from the inner and posterior aspect of the cæcum and had been curled upon the vena cava inferior. It had become gangrenous, and had sloughed away. The patient had been very ill nearly six days, and when I operated had a temperature of 103.5 F. and a pulse of 130. I found a large abscess, containing about two ounces of very putrid pus, in which the necrotic appendix was found almost unrecognizably disorganized. The median wall of the abscess cavity, in which the stump of the appendix lay, was an indurated, thick mass of tissue, so closely adherent to the vena cava inferior and the roof of the mesentery that I dared not try to dissect out and ligate the stump. The cavity was drained by a gauze pack, and the child's temperature and pulse have been normal ever since. The pack has been removed, and there is now only a healthy granulating cavity, which, under the careful treatment of the family physician, will soon be entirely closed.

This physician, for whom I have done a large number of operations, and who has always seen me remove the whole of the appendix, was somewhat alarmed and perhaps disappointed at my refusal to make a radical removal in this case. He had always seen me remove the stump or the whole appendix at its origin from the cæcum, and was fearful of the outcome of this case. He feared, no doubt, that the stump might give rise to immediate or remote trouble. I also shared this feeling, and I am of the opinion that the appendix should be completely removed in every case unless some such condition as I found here, which is fortunately very rare, should plainly contraindicate the removal of the stump. I think every surgeon gets to know the limitations of his technical skill, and I felt that my limit had been reached in this case. I doubted my ability successfully to remove the stump in this instance, and gave the patient the benefit of the doubt.

I do not intend to discuss the diagnosis of appendicitis. It is either very simple and certain, or very difficult and uncertain. The diagnosis of appendicitis is simple and certain in about ninety-nine per cent. of all cases, unless the attending physician has masked the symptoms by the administration of morphine or some other opiate. This is a very bad practice and cannot be condemned too strongly. I am happy to say that in St. Louis the opium treatment of peritonitis has been abandoned by the more enlightened members of the profession. One of the objects of this report is further to banish into oblivion this method of treatment.

I believe that when it comes squarely to the consciousness of the general practitioner that modern surgery in the hand of experienced operators can cure seventy cases of acute suppurative appendicitis in succession, without selection of cases, all other methods of treatment must be abandoned. And when it is further stated that the average time of confinement to the bed is less than three weeks, all room for discussion seems to vanish.

Two of the best physicians of this city have each called me to operate for appendicitis, when upon palpation of the abdomen I gave the opinion that the trouble was in the gall bladder. My opinion was immediately corroborated by the operation in both cases. I have done twenty-one operations for appendicitis in the practice of one of these physicians and sixteen in the practice of the other, and in all of these cases their diagnosis was correct. This proves that acute cholecystitis may be mistaken by very skilful and experienced practitioners for acute suppurative appendicitis. I have also met with a few cases in which the differential diagnosis between pyosalpinx and appendicitis was difficult. I have three times found both conditions present in the same woman.

About three years ago I was called to a neighboring village by a most competent physician, who had in consultation the most renowned pathologist and diagnostician of St. Louis. The latter gentleman had been in attendance since the previous night, and the diagnosis of ruptured tubal pregnancy, which was first made, had been abandoned, and both gentlemen were of the opinion that we were dealing with a case of appendicitis. I myself could not arrive at a diagnosis between the two diseases, and all of us were sure that it was one of the two conditions, and could be nothing else. The medical consultant, in whose judgment I have the greatest confidence, leaned somewhat toward the side of appendicitis. I made the incision for appendicitis, midway between the anterior superior spine and the linea alba at the lateral margin of the rectus muscle. Through this incision I evacuated several pounds of clotted blood and removed the most beautiful specimen of ruptured pregnant tube that I have ever seen. The patient made a most excellent recovery.

Twice I have found the appendix upon the left side of the body. In the one case the cæcum was attached to the last lumbar vertebra and the promontory by a short mesocæcum, while the appendix hung down into the left side of the pelvis and was attached by adhesions to the sigmoid flexure. In the other case there was a large abscess cavity, which started from the ulcerated free end of the appendix, and was situated to the left and in front of the bladder. In one case I found the appendix near the umbilicus, and the abscess surrounding it would have broken through the umbilicus if it had been left to nature. In all other cases in my entire experience the trouble was in the usual place—upon the right side, between the diaphragm above and the floor of the pelvis below.

It is not my purpose to discuss the etiology or pathology of appendicitis. I may say that I have found a foreign body in only two cases. In one it was a piece of solder; in the other a fragment of an oyster shell. I doubt very much whether or not these substances were etiological factors. Sometimes the fæcal concretions have a striking resemblance to a seed of some fruit, but I have never found conclusive evidence that seeds are the nuclei for these fæcal formations. By chemical analysis, however, I have frequently found bismuth and mercury in these concretions, and have entertained the idea that the administration of these heavy substances may prove to be a factor in their formation. Stoehr has recently proven that the follicles within the appendix are in a state of degeneration throughout the life of this rudimentary organ. Knowing this fact, we can easily understand that the

pathogenic bacteria will find a fertile soil in this organ, the mucous lining of which is undergoing a process of degeneration during the entire life of the human body.[1]

After the diagnosis has been made and the operation determined upon, I recommend the following management: The attending physician will order total abstinence from food or drink; he will order, or himself administer, copious injections of warm water into the colon, with a view of evacuating the contents of the bowel before the operation. I have never seen bad results follow the administration of calomel in broken doses or even the use of salts, and, if it were not for some theoretical considerations, I would recommend the administration of salts in every case in which it has been decided to operate. Theoretically, it might possibly be expected that in the case of a gangrenous perforation the patient might be purged into his own abdominal cavity, though practically—*i.e.*, mechanically—this seems to me very improbable indeed. I would consider the administration of purgatives perfectly safe in all cases after the lapse of forty-eight hours, because occlusive adhesions will have formed pretty securely by that time. The patient must assume the recumbent position in bed, and a moist antiseptic pack must be applied over the entire abdomen and left *in situ* until the surgeon arrives, be that two hours or twelve hours or longer. The belly should be soaped and shaved, even in hairless children, before the pack is applied, in order to allow the antiseptic solution more thoroughly to penetrate the epidermis.

The Operation of Appendicectomy.—The incision which I prefer, and invariably used in the cases now under consideration, is the one which, so far as I know, was first recommended for appendicectomy by Senn. It is the incision in the linea semilunaris, and by its use the abdominal wall can be opened without cutting through any of its muscles. The only tissue which is cut is connective tissue—*i.e.*, aponeurosis or fascia—and there is very little hemorrhage. The consequent hernia in the scar will depend upon the drainage that is necessary more than upon the incision or the method of suture which is chosen. The length of the incision is from two and one-half to four and one-half inches, and depends upon the dexterity of the surgeon and upon the position of the appendix. As my experience and skill have grown, I have been enabled to make smaller incisions, but in one case I was compelled, even recently, to make an incision eight inches long. In that case there was a large subphrenic and perihepatic abscess. The appendix extended along the posterior wall of the ascending colon and reached to the lower surface of the liver. I estimate the quantity of pus evacuated from this patient at one and one-half quarts. The best guide for the incision is the lateral margin of the rectus muscle, which can be easily felt or seen. The middle of the incision should be at about McBurney's point in ordinary cases. In other cases I make the middle of the incision over the most prominent portion of the induration, no matter where that may be. I have stated above that I advise operating as soon as the diagnosis is made. I estimate that the average time which had elapsed in this series of cases was about sixty hours. The shortest time was three hours, and the longest eight months since the beginning of the attack. The average time is made longer than it would otherwise be by one patient who had been continuously sick for eight months and by another who had been bedridden for six months.

I wish to emphasize here the peculiarity of some acute suppurative and gangrenous cases: that the temperature, and, in rare cases, also the pulse, will drop almost to the normal stage twenty-four or thirty-six hours after the beginning of the attack. The tenderness on pressure may also be lessened at this time, but this amelioration of the symptoms must never be looked upon as an indication to postpone the operation, or, as I knew it to do in one case, to lead the physician to doubt his original diagnosis. In that instance small doses of an opiate had been given and the operation was postponed for eleven days, when the high temperature and pulse returned. The boy's life was lost by the postponement, as was clearly shown by the operation. This case happened about eight years ago; the death was due to septicæmia. All subjects of appendicitis that have ever died, in my experience, were killed by septicæmia, and I believe that nearly all could have been saved by early operations or more prompt and more thorough work. I do not believe that there are cases of so-called fulminating or furibund appendicitis, in which the patient cannot be saved by prompt interference. In the series of cases which I am now reporting, there were six which fully fit the description of the "fulminating" examples we find mentioned in recent literature, and all of these patients recovered. I shall have a word to say later on about this line of cases.

In one report I find that the use of iodoform is made responsible by one physician for three deaths. When we stop to think of the harmlessness of iodoform powder, when compared to the deadly toxins produced by streptococci or the bacterium coli commune in cases of appendicitis, statements like the above appear ridiculous, and we must seriously doubt the diagnostic ability of the physician who will account for deaths following operations for appendicitis by the pretext that iodoform was used. The reason we remove the suppurating or gangrenous appendix is to get rid of the source of the septicæmia, and the reason we drain the wounds is to allow the escape of the toxins and pyrogenic substances that may be left after we have removed, mechanically, all that we can or dare by our surgical operations. If a death follows our operation, we must admit either that we could not sufficiently exterminate the cause of the disease, for some reason or other, or that the septicæmia had so poisoned and weakened the organism that the shock of the operation was too much for the patient to bear. Embolus, bronchitis, pneumonia, nephritis, etc., are all of septic origin, and so it seems clear that when we operate in cases of appendicitis we are trying to save our patients' lives from the dangers of septicæmia or its complications and sequelæ.

This view of the treatment of appendicitis clearly defines the relation of the medical man to the surgeon in the management of these cases. The physician calls the surgeon, because in him he has the weapon with which he can successfully cure the disease he has correctly diagnosed as a septic fever, having a local origin. This local trouble must be first removed, and then the physician can carry the case to a successful issue by the remedies he so well knows how to use. It seems to me that all discussions about the question as to whether a case of appendicitis is a medical or a surgical one are fruitless, when we bear in mind the facts which I have just presented. There is no better instance than this very one to prove that the physician and the surgeon are interdependent. Their work is very different and not conflicting. A physician who is looking out for the interest of his patient will call upon his friend, the surgeon, to perform an operation requiring great skill and a large experience in surgical work. He will select a man who devotes his attention to the science and art of surgery. He will select a professional surgeon and not an amateur. The most dangerous person to manage a case of appendicitis is one of those men who drives a general business, a dilettante in all the departments of medicine, a master of none. There are men in all our

[1] See Anatomischer Anzeiger, 1897, and Transactions of the Anatomische Gesellschaft, 1897.

large cities who, while posing as surgeons, will attend Mrs. Vandergold in confinement or one of her children who has "summer complaint." The careful, conscientious physician will not call one of this class to do an operation for him, if he can help it, because he is a dilettante in surgery; and not only that—he is also a competitor of the physician who calls him, and under our beautiful code of ethics may be called to the family into which he was introduced by the physician if there should afterward be a medical case in the same house. In large cities the highest and best results of medical work can be achieved by the division of labor. But the specialists must be honest and fair toward the family practitioner; they must not do family practice under any circumstances. The conditions are different in the country, as specialists cannot thrive in small towns and villages, and the country physician must help himself as best he can in emergencies; but he also must learn to select from the city specialists a professional and not an amateur for his consultant.

The incision having been made through all layers of the abdominal wall, an exploration is made of the parts that present themselves. Sometimes a piece of omentum, indurated and injected, will be found adherent to the cæcum, and this may be used as a guide to the appendix. By carefully loosening this piece of omentum from its attachments, the operator will always be led to the appendix. Before this work of disentanglement is begun, I have the two lips of the incision pulled apart by two broad retractors, and I spread broad pieces of gauze into the wound, so that any pus cavity that may be opened during the process of separating the conglomerated intestines will discharge its contents upon the gauze and not soil the healthy portions of the intestines. In some cases the best guides to the appendix are the tæniæ of the colon ascendens, which, if followed up, must lead to the root of the appendix. In other cases the last loop of the ileum will furnish a valuable landmark, as it can always be followed to the ileo-cæcal valve. In some cases it is not necessary to lift the cæcum out of the cavity, but in those in which the appendix is located under the ascending colon or behind the cæcum it is best to lift the latter and the last loop of the ileum, and by careful work with the fingers, bluntly separating the retroperitoneal connective tissue, it will be found possible to lift the whole mass out of the abdominal cavity.

In about one-half of my cases I had to lift the cæcum out of the cavity, in order to make a clean and perfect extirpation of the diseased appendix. In the other half of the cases the appendix was situated so that it could be followed to its root within the abdomen. These are the easy cases of appendicectomy. The difficult ones are those in which the appendix cannot be found without a tedious, time-consuming search among the old and fresh adhesions.

After the appendix has been found and carefully ligated off at its root, the peritoneum should be drawn together with a few stitches, so as to cover the ligature which surrounds the root. In nearly all cases a healthy stump can be formed by using the serosa and muscularis only, while the mucosa is cut short and buried. In one case the ligature slipped off, and I had amputated the appendix so close to the cæcum that I could not replace another. In that case I pulled the whole together in the cæcum with a few stitches as best I could, and covered these stitches with a piece of gauze, the end of which was conducted out of the incision.

The most important thing to insure the safety of the patient is always to place a strip of gauze upon and around the stump of the appendix, and to bring a piece of the gauze strip in contact with every portion of gut that is covered by the deposits of plastic lymph or that is in any way discolored or indicative of infection. I nearly always use three narrow strips of gauze, but sometimes only two, and sometimes four or even five. These gauze strips are from one inch to two inches broad, and about eighteen inches long. They act as capillary drains. I have generally used nosophen gauze, but in some cases bichloride or simple sterile gauze.

Before the operation is complete, the operator must in every case pass his finger into the pelvic cavity; and if it contains pus or serum this must be taken out through a glass tube, and after all of it has been drawn out or wiped out with gauze it is well to have a drain of some kind in the cul-de-sac for a day or longer. In the series of cases I am now speaking about, the cul-de-sac was drained in four. They were cases in which general peritonitis with purulent effusion existed, and in which many of the loops of intestines were glued together by exudates of greenish-yellow lymph. I do not recommend flushing the general cavity in these cases, and, in fact, limit the use of irrigation as much as possible. In several of the cases I did resort to irrigation of circumscribed abscess cavities, but in none did I flush the abdominal cavity.

The gauze strips or glass tube in Douglas' cavity being satisfactorily adjusted and projecting out of the incision, a few through-and-through stitches are now inserted at both angles of the incision, it being made certain that the drains are not crowded or compressed by the sutures. The dressing consists of absorbent antiseptic gauze and cotton in sufficient quantity to retain the fluids which drain out of the wound. These dressings need not be changed until they appear to be saturated with fluids. I usually leave them alone for forty-eight hours, and if the pulse and temperature are normal they may be left longer. When they are soiled they may be changed, for æsthetic if for no other reasons.

The after-treatment consists in rest in bed, liquid diet, and gentle purgation. If there has been no free evacuation of the intestines before the operation, I order one-tenth grain of calomel every hour until flatus or stool passes. I order its administration twelve hours after the operation, and follow this with a gentle saline—preferably a Seidlitz powder or citrate of magnesium. I allowed most of these patients to sit up on the tenth day, and to begin to walk about a few days later. The average time in the hospital or sick-room was about twenty days.

It appears, then, that of the seventy consecutive cases of suppurative or gangrenous appendicitis, every single one was treated by means of gauze drainage, to which was added in some cases a glass tube or a rubber tube. I will add that in all but one of the cases the appendix was perforated, four cases were complicated by general peritonitis, and at least six would have been called fulminating by those who have described this variety or species of appendicitis. I say at least six, because the notion or definition of fulminating appendicitis is an elastic one, and what might appear fulminating to one observer might appear ordinary to another.

In conclusion, let me say a few words about the prognosis of appendicitis. According to the experience of many physicians, surgeons, and pathologists, there are a great many cases that end in recovery after the first attack of appendicitis. These run their course, and seem to recover without suppuration. They have been called catarrhal appendicitis. I have not seen many cases of this description so clearly demonstrated that there could not be a reasonable doubt in the diagnosis.

The regular autopsy books at Heidelberg and at Hamburg have been searched, in order to determine approximately how many cadavers that are examined upon the post-mortem slabs have passed through this

disease, now known as appendicitis, but in these reports called perityphlitis and typhlitis. It can be shown that a very large number of persons had passed through suppurative appendicitis without operation, and many lived for years afterward. In many cases perforation of abscesses into hollow organs had taken place, and one could see plainly that these unfortunates had passed through months and years of invalidism. These results were achieved under the expectant plan of treatment, and I know from personal observation at Heidelberg that they were treated by the regular and continuous administration of opium. Of course there were thousands of cases of "idiopathic" peritonitis in men, which were in reality appendicitis, that went to the dead-house, and, because the trouble was not traced to the appendix, figured on the hospital lists as cases of general peritonitis. I have seen the pathologist, after making the usual routine examination of the organs according to Virchow, stop at the diagnosis of general peritonitis, when he would nowadays invariably say "peritonitis septica ex perforatione aut gangræna processus vermiformis cœci," because he would find that the appendix was the seat of the original affection.

I believe that considerably more than half will recover from the first attack without operation. I believe that twenty per cent. of all cases of appendicitis will terminate fatally, if not operated upon, from septicæmia, either in the first or in a succeeding attack.

I believe that two cases out of one hundred, or perhaps two out of one hundred and fifty, will terminate fatally in the hands of expert operators for appendicitis. Errors of judgment in operating upon cases that are hopelessly septic will probably always keep the death rate that high. It is sometimes very difficult to estimate the virulence or destructiveness of the existing toxæmia, and a case will occasionally slip in that will baffle the judgment of the most careful surgeon.

I will give it as my conclusion that the safest plan of management of all cases of appendicitis, take them as they come, is the immediate removal of the appendix and the drainage of the infected cavities. This plan of treatment will be followed by the very satisfactory record of about ninety-eight per cent. of recoveries.

The expectant plan in a large percentage of the cases will lead to a late surgical operation, and in about ten per cent. of these cases will lead to death. Those patients who are fortunate enough to recover from well-marked attacks of appendicitis will pass through a prolonged siege of dangerous illness, and may never regain a robust constitution.

Finally, I want to add that every patient suspected of having appendicitis, in whom the symptoms are grave or protracted, should be seen by one who is familiar with the disease, and by one who has become accustomed to operating for its relief.

Union Trust Building, October, 1897.

Tic Rotatoire.—Meyer (Freiburg) draws the following conclusions from five accurately observed cases: 1. Tic rotatoire depends in the majority of cases upon functional disturbances of the brain, and is caused by mental or physical excitement. 2. In rare cases it depends upon organic changes in the brain, these changes, as a rule, being situated in the cerebellum. In some cases it is very likely that disease of a centre in the frontal lobe may give rise to tic rotatoire (Dickinson). 3. Tic rotatoire may depend upon pathological changes in the course of the spinal accessory nerve itself, or in its branches supplying the sterno-cleido-mastoid and trapezius.—*Wiener klinische Rundschau*, January, 1898.

Progress of Medical Science.

Tubercle Bacilli in Butter?—L. Rabinowitsch (*Zeitschrift für Hygiene*, 1897, xxii., 1, p. 90) made a series of experiments, thirty in Berlin and fifty in Philadelphia, in which various samples of butter were examined for tubercle bacilli. The true bacillus was not found, but in thirty or forty per cent. of the specimens a micro-organism nearly analogous to it. The latter stains as does the tubercle bacillus, and morphologically cannot be distinguished from it. In the case of guinea-pigs these bacilli are less pathognomonic than the tubercle bacillus, inasmuch as when brought into the peritoneum in small numbers they may remain inactive: however, the guinea-pigs lose weight very rapidly and die. Post mortem the cases resemble "inoculation tuberculosis." The entire peritoneum and mesentery are studded with tubercles; the mesenteric glands are swollen and contain in part a cheesy, purulent substance. The liver is also studded with tubercles, which seem more as if they were upon rather than in the liver. The spleen is in mild cases only enlarged, now and then filled with tubercles. The lungs show frequently numerous transparent small tubercles, which, however, are only superficial and do not enter deeply into the substance of the lung. In the tubercles and the affected lymph glands micro-organisms very much resembling the tubercle bacillus can be demonstrated. Typical giant cells, such as are often found in tuberculous processes, are never observed. The inoculated animals do not react to tuberculin. The cultivation of the micro-organisms is far easier than is the case with the tubercle bacillus. The growth is more luxuriant than that of the tubercle bacillus, and takes place, though more slowly, at the room temperature. In the glycerin-bouillon culture the micro-organisms form traces of indol, and the bouillon is rendered cloudy upon the addition of an acid, which is not the case with the true tubercle bacillus. The new bacilli form a yellow or copperyred substance, which is never seen with the true tubercle bacillus. Instead of the agreeable cauliflower odor of the true tubercle bacillus culture there is in the culture of the new micro-organisms a disagreeable ammoniacal smell.

Tetany in Childhood.—Th. Escherich (*Berliner klinische Wochenschrift*, 1897, No. 40) distinguishes the following forms of tetany in childhood: 1. The most frequent form by far is the tetany of rickets (idiopathic tetany). Intermittent form (spasms of short duration, often painful, marked increase of electrical and mechanical irritability, acute or subacute course, tendency to recur). This form of tetany often happens without spontaneous spasm: that is, it is latent; this latent form of tetany can be constantly demonstrated in those nurslings who suffer from laryngismus stridulus. According to the opinion of Escherich, tetany is not the result of rickets, but both conditions are due to the same poisons (vitiated atmosphere). 2. Tetany in diseases of the stomach and intestines. Abrupt onset: intermittent painful spasms in the extremities; in the interval Trousseau's and the facial (Chvostek) phenomena; all the foregoing following acute indigestion. Cure in a short time. In this form are met cases with persistent contracture. 3. Tetany in infectious diseases. Escherich observed one case after pneumonia and nephritis; transient Trousseau and facial phenomena. Cure in eight days. 4. Pseudo-tetanus. Thus far the case of Kjellberg is the only one in literature. The picture of the disease, which reminds one strongly of tetanus traumaticus, consists of trismus and a general rigidity, so that the patient lies stiff in bed. During rest as well as in sleep

the rigidity diminishes, but never entirely disappears. On the contrary, through external irritation as well as spontaneously, paroxysms may occur which may lead to painful contractures. Arms, hands, and eyes can be freely moved in some cases; no Trousseau, no increase of galvanic irritability. The condition remains unchanged for from three to six weeks, when recovery slowly begins and finally a cure results; no recurrence. Perhaps hysteria plays a part in these cases.

Relationship between the Testicles and Prostate.—R. Floderus (*Deutsche Zeitschrift fur Chirurgie*, xlv.) draws the following conclusions: *A*. Effect of bilateral removal of the testicles. 1. If undertaken before puberty, aplasia results. 2. In adults a prostate which before operation was not pathological shrinks after the operation. 3. In cases of beginning or developed prostatic hypertrophy the influence of the operation is less uniform and at times not demonstrable. The diminution in size is greatest in the upper part of the organ. 4. Tuberculous processes, as well as chronic prostatitis, may be brought to a standstill or even cured by the operation. *B*. Effect of unilateral removal of the testicle. 1. If the prostate be normal, the operation as a rule causes an atrophy of the corresponding lobe, which is noticed principally at the upper half. 2. The operation will not prevent the existence of prostatic hypertrophy. 3. Existing hypertrophy is influenced only now and then, and in those cases in the corresponding lobe. 4. Tuberculous processes in the prostate lobe of the same side may be brought to a standstill and at times cured. 5. The opposite prostatic lobe is not influenced, which fact leads us to suppose that the nerves (vasomotor, secretory, trophic) play a part here. 6. As a rule the operation causes atrophy of the corresponding seminal vesicle as well as compensatory hypertrophy of the opposite testicle and seminal vesicle.

Apropos of Urethral Strictures.—J. Verhoogen (*Journal de Médecine de Bruxelles*, 1897, No. 421) draws the following conclusions: 1. Electrolysis is of service only at the beginning in the treatment of soft and localized strictures, when the patient is pressed for time and desires to be rid of the trouble. As after-treatment, dilatation is absolutely necessary. 2. Internal urethrotomy is to be reserved for those cases in which an immediate dilatation is called for, *e.g.*, when urinary fever threatens the life of the patient, or in cases of threatened sepsis and kidney disease. Carried out under aseptic conditions, the operation is harmless. The operation may be followed by dilatation at a later period. 3. External urethrotomy will seldom be found necessary. It is undertaken in urinary abscesses, urinary fistulæ due to stricture, and in cases of impermeable strictures, if such at all exist.

Skin Lesions in Acute Articular Rheumatism, together with Remarks upon the Nature of Erythema Multiforme.—G. Singer (*Wiener klinische Wochenschrift*, 1897, No. 38) observed as accompanying manifestations of rheumatism seven cases of polymorphous erythema, and in one case found the staphylococcus pyogenes albus in the skin eruption. Furthermore, in a case of purpura rheumatica he was able to demonstrate the streptococcus pyogenes in the blood; in another case the staphylococcus pyogenes albus in the urine. Symptomatically, erythema multiforme appeared most frequently in generalized pyæmic processes; secondly, in articular rheumatism. But even that form which the dermatologists consider idiopathic showed in its invasion and course such an intimate connection with articular rheumatism that in the majority of cases one was forced to think of a rheumatic process in which the joint symptoms were situated in the background. Often enough the skin eruption is but a local manifestation of the microorganisms (staphylococci and streptococci) in the circulating blood. Therefore we are to look upon erythema multiforme as a pyæmic skin disease *par excellence*, and, since it bears such a close relationship to acute articular rheumatism, it is but natural to reckon the latter among the pyæmic diseases.

Excretion of Iodothyrin through the Milk.—Ivar Bang (Christiania) reports the case of a child with congenital struma, in whom the circumference of the neck was diminished four centimetres during the period of nursing, the mother having been given iodothyrin with the view of diminishing the size of her thyroid. With the mother as with the child the drug lost its efficiency the longer it was used. Inasmuch as the child's nourishment consisted of mother's milk only, and inasmuch as the child received no medicine whatsoever, Bang concludes that the good results in the child were due to the excretion of iodothyrin in the milk of the mother.—*Wiener klinische Rundschau.*

Causes of Subnormal Temperature.—Dr. Janssen sums up the causes of this condition as follows: 1. After the direct withdrawal of heat from the body, as in cases of exposure of unconscious or drunken persons in a very cold atmosphere, or after immersion in very cold water. 2. After the loss of great quantities of fluids from the body, as in severe diarrhœa, enteritis, cholera, or profuse hemorrhage. 3. In conditions of cachexia and inanition, such as cancer of various parts of the alimentary canal, severe forms of diabetes, pernicious anæmia; during convalescence from febrile affections; and in many chronic mental diseases. 4. In grave circulatory disturbances, as in cardiac failure. 5. In various diseases of the central nervous system, in tuberculous meningitis, at the onset of cerebral hemorrhage and embolism, in some cases of brain tumor, and in general paralysis of the insane. 6. After irritation of sensory nerves, as in intestinal strangulation, in renal and gall-stone colic, internal perforation of the intestines, etc., and after surgical operations. 7. In skin affections involving large areas, such as scleroderma and extensive burns. 8. After fevers, when the temperature may long remain subnormal, or in the course of certain fevers, as in pyæmia. 9. In cases of poisoning by phosphorus, atropine, morphine, carbolic acid, and in alcoholic intoxication; also in the auto-intoxication of uræmia and in diabetic coma. In some healthy persons subnormal temperatures are occasionally observed without any apparent cause.

Oxyphenylsulphonic Acid as a Test for Albumin.—

R Ac. oxyphenylsulphonici	3 parts.
Ac. salicylsulphonici	1 part.
Aquæ	20 parts.

One drop of this solution to one cubic centimetre of urine gives a white transparent precipitate of albumins. Peptone, propeptone, alkaloids, urates, and phosphates are not precipitated.—Bourceau, *La Médecine Moderne.*

Infectious Diseases during Pregnancy.—Dr. Jacub at the recent International Medical Congress at Moscow drew the following conclusions: 1. Pregnancy does not protect a woman against any of the infectious diseases. 2. The danger to the child is very great, and greatest in recurrence. 3. The higher the temperature, the greater the danger. 4. The death of the fœtus depends not only upon the height of the temperature but also upon the direct transmission of the disease from mother to child. 5. A systematic antefebrile therapy must be thoroughly carried out. 6.

In typhoid fever the course of the pregnancy is usually interrupted during the second week. 7. Prognosis for the mother is no worse than in the non-pregnant state. 8. Infection may take place at any time during the course of pregnancy.—*Wiener klinische Rundschau*, January, 1898.

Herpes Zoster and Facial Paralysis.—Eichhorst (*Centralblatt fur innere Medicin*, 1897) reports the case of a woman, aged twenty years, in whom a few days after a total right-side facial paralysis a herpes developed which involved the lower outer half of the right ear, the right external auditory canal, the right half of the tongue, and the mucous membrane of the right half of the hard palate as well as the right half of the uvula. Inasmuch as the sense of taste was fully intact, Eichhorst concludes that the chorda tympani conveys two sets of fibres, those which govern the sense of taste, and those which give rise to trophic (herpes) changes.

The Cerebral Complications of Raynaud's Disease.—Osler (*American Journal of the Medical Sciences*, November, 1896) reports three cases of the above, in the first of which during six winters the local asphyxia was complicated with epileptic attacks and hæmoglobinuria. In the second case during a period of five years there were attacks of local asphyxia developing into gangrene and followed by unconsciousness, aphasia, paralysis (monoplegia and hemiplegia), and terminating in coma and death. The third case, that of a girl thirteen years of age, was complictad with hysterical attcks.

Rupture of Aortic Aneurism into the Bronchus.—At a meeting of the Edinburgh Medico-Chirurgical Society, held on January 19th, Dr. Bruce showed a specimen of great interest and rarity—the rupture of an aortic aneurism into the bronchus. The aneurism occupied the transverse part of the aorta and the first part of the descending aorta. There was a small secondary sac also, which was directed toward and into the left bronchus, compressing it entirely. In the corresponding lung a condition of "aneurism phthisis" was set up. The lung was completely consolidated and contained many small caseous nodules. There was also complete pleural adhesion. The patient had been much exposed, and on admission presented the symptoms of acute pneumonia; his temperature was high; the lung was extremely dull below and presented the Skodaic note at the apex. So dull was the basal note that four aspirations were made with negative results. This consolidation extended up the lung toward the apex. The patient's temperature remained irregular, but he was thought to be improving; when coughing, he was seized with bleeding and almost immediately died. The diagnosis was rendered obscure by there being no displacement of the heart and no abnormal heart sounds.—*Lancet.*

Colles' Law and its Exceptions.—Dr. Hochsinger has published, in the *Medizinische Wochenschrift*, some interesting articles on Colles' law and its exceptions. He is of opinion that, although there is no reason for supposing a syphilitic retro-infection of the mother from a fœtus affected with syphilis, it must nevertheless be conceded that there is a retroaction of the fœtus on the mother, a retroaction which has the effect of producing a certain amount of immunity of the mother against syphilitic infection. Dr. Hochsinger's explanation of this retroaction is in accordance with that given by Finger and Duhring. He believes that the corpuscular infective material of syphilis is not able to pass through the placenta from the fœtus to the mother, but that the toxins originating in the blood of the syphilitic fœtus pass by diffusion into the vascular system of the maternal placenta and immunize the tissues of the mother against infection. As this immunity depends on the amount of the toxins and also on the length of time during which they have been acting on the maternal tissues, it is easy to understand that both the degree and duration of Colles' immunity may be variable. If only a small quantity of immunizing material has been transmitted from the fœtus to the mother, her immunity will be very limited and she will be capable of contracting syphilis at a comparatively early date, or she may even be infected by her own child. This explanation fully accounts for all the exceptions to Colles' law. It is also obvious that a woman's chance of being rendered immune against syphilis increases with the number of her pregnancies by a syphilitic father. Dr. Hochsinger said that twenty cases of exception to Colles' law have been recorded during the last sixty years, only four of them being in women who had been infected after having more than once borne children which had inherited syphilis from the father; in the remaining sixteen cases infection took place after the first pregnancy. The history of the cases further shows that about half of the infants which ultimately infected their mother did not display any symptoms of syphilis at the time of birth, but developed them during extra-uterine life. As to Fournier's theory of "syphilis par conception," Dr. Hochsinger conceded the possibility of a syphilitic man infecting his wife during her pregnancy, a case which may occur when the man was free from disease at the time of conception, but contracted it subsequently. After impregnation by a syphilitic man some time is required for a sufficient quantity of immunizing material to pass from the fœtus into the vascular system of the mother, and lateness of the fœtal virus in becoming active increases the possibility of the mother being subsequently infected. If, therefore, the mother of a syphilitic infant shows secondary symptoms without having had any primary infection during pregnancy, that must not be "syphilis par choc en retour." Weil and Neumann have reported cases of primary indurations in women who were pregnant with children infected with syphilis by the father. Neumann has also recorded a case in which a woman, pregnant with a syphilitic fœtus, was affected with an initial sclerosis in the eighth month. —*Lancet.*

Ear Muscles of Accommodation.—Dr. Rumbold, Sr., says that the functions of the middle-ear muscles are to select and amplify such sounds as the listener desires to hear most distinctly; making it appear that the ears have muscles of accommodation quite analogous to those of the eyes.

Antipyrin in Dysentery.—Ardin-Delteil (*Montpellier Médical*, 1897, No. 42) reports a case of severe dysentery treated with enemata of antipyrin. After frequent injections the profuse diarrhœa ceased, the strength of the patient improved, and finally a cure resulted.

Ptosis as a Symptom in Abscess of the Temporal Lobe.—Steinbrügge (*Deutsche medicinische Wochenschrift*, 1897, No. 41) reports the case of an abscess in the temporal lobe of the brain secondary to purulent otitis media, in which ptosis of the corresponding upper eyelid formed an interesting symptom. This combination was first brought to the notice of the profession by Körner. In the opinion of Steinbrügge the ptosis in this case was not due to a spasm of the orbicularis palpebrarum but to a paresis or weakening of the innervation to the levator palpebræ. At any rate, as a corroborative symptom in this condition, ptosis is worthy of note.

MEDICAL RECORD:

WOMEN DOCTORS IN THE DIFFERENT COUNTRIES OF THE WORLD.

THIS country is undoubtedly the happy hunting-ground of the woman doctor. The increase in her numbers has within the last twenty years been phenomenal. It is estimated that there are now about forty-five hundred woman practitioners in America as against five hundred and twenty-seven in 1870. The majority of these are of course general practitioners, but there are as well homœopathists, hospital physicians and surgeons, professors in schools, specialists for diseases of women, alienists, orthopedists, oculists, aurists, and electrotherapeutists. Doubtless like their brothers they suffer from the stress of keen competition, but it is stated that most of them succeed in making good headway, while one or two of the leading lights are credited with amassing the eminently satisfactory income of $25,000.

In Great Britain a vehement prejudice has existed for many years against admitting women into the ranks of the medical profession, and even at the present time the principal medical schools in that country refuse to concede to women the privileges enjoyed by men. This feeling is, however, slowly but surely dying out, and the prediction may be made with confidence that ere many years have passed the restrictions in the way of women will be removed, and that they will be enabled to pursue their medical course and be granted their diploma on equal terms with men. In fact, notwithstanding the numerous obstacles to be overcome, there are now numbers of women practising in all parts of the kingdom, with fair success. The most fertile field for the employment of English medical women is in India, where owing to religious scruples men are not allowed to attend the native women. The introduction of vaccination into Afghanistan was entirely due to the efforts of an English woman doctor who holds the responsible position of medical adviser in chief to the Ameer, and who is said to possess much influence over that fierce despot. In Germany also there are few woman physicians, although signs are not wanting which point to a new departure in this respect. Austria can boast of only two feminine practicers of the healing art; the first was licensed a few years ago, and the second within the past eighteen months secured the degree of doctor of medicine at the University of Vienna. Nevertheless it was only with great difficulty that she obtained recognition of her diploma; a ministerial decree was necessary to bring about this result, though she had passed all her examinations at the University of Vienna. Perhaps the most notable advance in the direction of light and civilization is in the case of China, the very home of distrust and suspicion. A Chinese woman doctor who obtained her degree in this country is now practising in the Flowery Land, and has charge of Siang-Hu Hospital at Foo Chow. This woman is the first and only one to practise medicine in her native land, but three other young Chinese women have become doctors of medicine in America. Abyssinia, which under the guidance of her European advisers has lately been asserting herself in many ways, has naturally been invaded by the woman doctor, and it is reported that the up-to-date Emperor Menelek has recently appointed a young Swiss lady from the University of Zurich to be physician to his household. Among individual cases of woman-doctor curiosities, that of the Armenian Princess Beglarion is perhaps the most interesting. This lady, possessed of both wealth and position, sacrificed all in order to become a doctor. She is but twenty-seven years of age, but has already achieved great fame in the East. The princess took her degree at Berne, after which she spent some time in the cholera hospitals of Russia. She now practises on her father's estate, where last year she built a hospital. As apothecaries and chemists, too, women are entering the lists with men. This is especially the case in England. Several of the London hospitals employ female dispensers, who are said to perform their duties in a thoroughly efficient manner. As regards woman dentists, America may be said to have almost the monopoly. Statistics show that there are in this country three hundred and thirty-seven. The foregoing details are instructive, insomuch as they tend to press home the already well-known fact that women are entering into competition with men in every profession and trade. The rush by women to enter the medical profession has in recent years been most marked, and it may be taken for granted that the increase of women doctors with the present facilities for gaining a degree will continue. The competition by women has as yet affected the profession in Europe to a scarcely appreciable extent, but here, where there are between five and six thousand female practitioners, the situation gives rise to serious reflection. Whether one believes or not that to practise medicine is a fitting career for a woman is outside the question; it would be altogether in opposition to the spirit of the age, if not impossible, to stay any forward movement. The lady doctor is a "*fait accompli*," and she is here to stay.

Typhoid Fever in Philadelphia.—The number of cases of typhoid fever in Philadelphia greatly decreased last week, and there were only seven deaths from the disease, ten less than in the preceding week.

THE TREATMENT OF MIDDLE-EAR DISEASE COMPLICATING THE EXANTHEMATA.

An interesting article on this much-discussed question appeared in the January number of the *Journal of Laryngology*. It is a plea for the abandonment of paracentesis of the drum membrane as a routine measure, and the substitution therefor of a plan of treatment which has simplicity to commend it, and which, in the experience of the writer, Dr. Robert H. Woods, of Dublin, has yielded surprisingly good results. He believes that purulent otitis before rupture of the membrane and establishment of the discharge is rarely met with, and that paracentesis in these cases as a routine measure is unjustifiable. The reason of this is that many of these cases are really aseptic, and, if left alone, would never discharge at all. Suppuration may supervene accidentally, either through some fault in the antisepsis at the time of puncture or subsequently by the infection of the serous discharge through inadvertence on the part of the patient. The serous fluid in the drum ought not to be looked upon or treated as purulent, but rather as a simple or perhaps conservative exudation provoked by a severe irritation. There is a possibility that sedative treatment will allay this irritation, and, by causing the fluid to become absorbed, obviate rupture of the membrane and suppuration.

In a certain line of cases the following plan of treatment was adopted: A saline purge was first given, and then one of the ovoids recommended for furuncle of the external meatus was applied to the ear. These ovoids are torpedo-shaped masses of jelly, weighing about four grains, having for their basis a mixture of gelato-glycerin and water, in such proportions that they remain gelatinous at ordinary temperatures for an indefinite time, while melting at the body temperature. The proportion of water is such that they neither dry nor deliquesce. In the process of making, one-sixth of a grain of the extract of opium is incorporated into each mass. One of these was placed in the meatus, which was plugged with wool. The ovoid melted, bathing the tympanic membrane, thus giving the drug an opportunity of exercising its influence. As a result of this form of treatment, the pain was relieved, the throbbing noises ceased, and after some days the process subsided, the fluid becoming gradually absorbed and hearing being restored. The plan has the advantage that, when it succeeds, the patient is relieved from the dangers attendant upon suppuration and the pain also is relieved as completely as by incision.

The pathological process in this class of cases is generally evoked by extension of an inflammatory process along the Eustachian tube. The question then arises, What is the precise part played by bacteria in this disease? A microscopical examination of the fluid when it first flows shows a few leucocytes, epidermal and epithelial scales, but very few bacteria. These latter increase rapidly, and in twenty-four hours practically make up the entire discharge. This state continues until true pus makes its appearance. As long as the membrane remains intact, the condition of the fluid remains without visible change, and the bacteria in the drum are prevented from or at least enormously retarded in developing. But when the fluid once gains access to the meatus, the causes which prevented the multiplication of the bacteria come to an end. This shows clearly that the date of the formation of pus is determined only by the time of incision or bursting of the membrane, and is therefore independent of the time the otitis has been established, but this could not be the case unless the fluid retarded the growth of the bacteria.

Under these circumstances we must regard the fluid as part and parcel of the living body, as in itself endowed with life—as, in a word, like a fluid tissue having for its special function the termination of bacterial invasion by the destruction of the invaders.

From the foregoing line of reasoning, absorption of the fluid before its volume or other cause leads to rupture of the membrane is to be obtained if possible. The author has used the ovoids above described, incorporating therein liquid extract of opium, cocaine, and sulphate of atropine. Figures are given to show the efficacy of this plan of treatment, which he believes will succeed in many cases. He is not a foe to paracentesis, although he does not believe that it is a *sine qua non* in the treatment of cases of acute otitis media. But he does object to its routine performance in every case, whether the malady results from the exanthemata or apart therefrom. He admits that his opinions will be freely challenged, but asks for his views the courtesy of fair treatment and the test of clinical experience.

TRAINING OF THE DEAF.

Most people are aware of the enormous difficulties to be encountered in teaching the deaf to speak, and when a child is stone deaf these difficulties are greatly enhanced. For many years the methods of instruction used with the deaf were crude and ineffective; now, however, great progress in the direction of rational teaching of the deaf has been made, and although the systems in force are none of them free from defects, still on the whole the results from the different modes of instruction have been very satisfactory. If the obstacles in the way of teaching the deaf are not easily surmounted, in the case of the deaf and dumb they are infinitely greater. In the early times the opinion was universal that it was impossible to educate the deaf and dumb. The theory then held was that language could be acquired only by means of the ear; consequently these afflicted children were allowed to grow up without any attempt being made to educate them, and they were practically ostracized. In some countries, indeed, this prejudice was carried to such lengths that children who were born deaf and dumb and were still in that condition at the age of three years were destroyed.

Fortunately any such views are now quite obsolete, and under the improved arrangements of the present day almost every deaf and dumb child not only receives an ordinary elementary education, but also manual instruction, which in many instances enables

him to earn his own living and to become, instead of a helpless burden, a useful member of society. This country is well to the front in providing ample facilities for the instruction of deaf mutes. The Columbia Institution at Washington, for the deaf, dumb, and blind, is a model of its kind, for not only is it the sole college in the world for the deaf, dumb, and blind, but it is also the only institution where such individuals can acquire a complete education. There has recently been issued from the Volta Bureau for the increase and diffusion of knowledge relating to the deaf a pamphlet containing the latest available statistical data in regard to the character of existing schools for the deaf, the methods employed in instruction, and other facts of special interest collected from all parts of the civilized world. It appears that the total number of schools for the deaf in different portions of the globe is 546. In Africa, Asia, and Australia there are 17; in Europe, 420; and in North and South America, 109. Of the 17 schools in Africa, Asia, and Australia, 7 are boarding, 2 day, 4 boarding and day, and 4 unclassified. In Europe there are 152 boarding, 130 day, 74 boarding and day, and 64 unclassified. In North and South America there are 62 boarding, 31 day, 12 boarding and day, and 4 unclassified. In Great Britain the boarding-school system is the favorite one. In Germany the day schools predominate. In the rest of Europe the boarding-schools contain about twice the number of pupils that are found in the day schools, and the day and boarding about two hundred more pupils than the day schools. In the United States the system in vogue is almost wholly the boarding.

Owing to the lack of clearly stated, uniform, and generally accepted definitions, any attempt to classify the schools according to methods would prove misleading and result unsatisfactorily. The bureau therefore does not attempt to classify the schools according to methods, but has simply divided the pupils into two great groups—the one group embracing all taught by speech and other vernacular means, the other by the sign language and any or all other means. In Africa, Asia, and Australia, out of a total of 502 pupils 300 are taught by speech and other vernacular means, 127 by the sign language and any or all other means, and 75 are unclassified. In Europe, out of 22,274 pupils, 18,176 are taught by speech and other vernacular means, 3,778 by the sign language and any or all other means, and 320 are unclassified. In North and South America, out of 10,201 pupils, 3,382 are taught by speech, etc.; 6,814 by sign language, etc.; and 5 are unclassified. The pupils in Great Britain have rathe more than half their number taught by articulati and lip reading. The teachers in the German sch for the deaf are compelled to undergo a sear examination by a board of specialists befo names can be entered upon the register for which may occur. A similar practice Sweden and other Scandinavian countrie France, and Austria offer opportunities tificates of qualification, but mandator ently do not exist.

From the foregoing account the fa

served that the great point of difference between European schools for the deaf and those in this c try is in the mode of instruction. In Euro teaching by articulation and lip reading while in this country the sign and manual is still the method of instruction chiefly rel

Mr. Gallaudet, in his report to the b Columbia Institution for the Deaf and " Nothing in my foreign investigations question the character of the foundatio system of instruction pursued in our A tions is based." This report, howe some time ago, and since then the o have somewhat veered round in fav method of teaching.

patients within its walls. She also hired nurses and other attendants, and relieved the necessities of the starving outside of the hospital.

Obituary Note.—Dr. H. Bedell Crane, of Newark, N. J., died at his home in that city on March 23d, of pneumonia. He was a graduate of the medical school of the University of Pennsylvania in the class of 1882.

Small-Pox in Kentucky.—There is a general smallpox scare over eastern and central Kentucky. The disease began at Middlesboro and spread to Artemus, where there are fifteen cases, and to Richmond, where twenty negroes have it and where the schools are closed. The State board of health and the United States authorities are believed to have the epidemic under control now at Middlesboro, and the State authorities will assist the health officers of Richmond in stamping out the disease there. The city council of Lexington has passed a vaccination ordinance, to be enforced by city physicians.

Pensions for Medical Officers in State Hospitals for the Insane.—A bill has recently been placed before the New York State legislature by Senator Page, providing a pension for officers in the State hospitals who have become physically disabled by reason of injuries or illness incurred or contracted while in discharge of their duties. It requires a continuous service in the State by the applicant of at least fifteen years. Those who have been in service fifteen years shall receive annually for life a sum equal to one-third of the annual salary received at the time the pension is granted; those twenty years in service, one-half the annual salary. The State commission in lunacy shall investigate all applications for pensions, and has the power to grant them, subject to the approval of the governor. All such pensions are to be paid out of the annual appropriation for the support of the insane. The bill was referred to the senate committee on finance.

The Chair of diseases of the eye, ear, and throat, at the Medical College of Virginia, made vacant by the death of Prof. Charles M. Shields, will be filled at the annual meeting of the board of visitors of the college, April 21st. All applications, accompanied by credentials, should be forwarded to Christopher Tompkins, M.D., dean, Richmond, Va.

A State Colony for Consumptives.—At the suggestion of Dr. John H. Pryor, of Buffalo, a resolution has been introduced into the New York senate relative to the establishment of a colony for consumptives the State Forest reserve, and calling for an investiı and report by the public-health committee of ıate as to the advisability of establishing such The committee in its report said that it ter for serious consideration by the State point of political economy, because of the eaths from consumption annually (thir-, which entailed a great financial loss; setts had established such a colony; York City had appropriated $60,000 for

the proper care of these unfortunates. The committee recommended that a committee of five be appointed by the legislature to make further investigation during the interval of the session and report to the next legislature. The report was referred to the finance committee.

The Astoria Hospital will, it is said, probably close its doors as soon as the present patients are well enough to be removed. The reason for this is that, under the new charter, the city authorities cannot send public patients to the institution, and it cannot be successfully conducted without the income derived from them. The hospital was built three years ago. Besides the public wards, the hospital contains a number of private rooms endowed by residents of Astoria. There is a training-school for nurses connected with the institution. Before the final steps are taken, however, one more attempt will be made by the managers to keep the hospital open. It has been suggested that the hospital be converted into a branch of some institution in the borough of Manhattan, specifically mentioned by the charter in the list of those entitled to receive assistance from the city. If the managers are not successful in securing such recognition of the hospital, there will be no other alternative than to close the institution.

The Chicago Home for Incurables has recently received a gift of $40,000 from Mr. D. B. Shipman, of that city. The money will be used for the building of additional wards.

The Woman's Medical College. — There was a reception at the new building of the Woman's Medical College of the New York Infirmary, at No. 321 East Fifteenth Street, on the occasion of its opening on Thursday, March 31st. The old college building was burned in April last, and its rebuilding has just been finished. The infirmary, of which the college is an outgrowth, was established in 1854 by Drs. Elizabeth and Emily Blackwell. The college itself was incorporated some years later.

The Medical and Chirurgical Faculty of Maryland.—The annual meeting of this society will be held in Baltimore on April 26, 27, 28, and 29, 1898. The annual address will be delivered by Dr. William T. Councilman, of Boston, formerly of the Johns Hopkins University.

A Committee for the Study of Tuberculosis.—The Academy of Sciences of Paris has appointed a committee, consisting of the members of the section of medicine and surgery, the two permanent secretaries, and MM. Brouardel, de Freycinet, de Jonquières, Chauveau, Duclaux, Arm, Gautier, to study the question of the spread of tuberculosis and the best means of preventing it.

The Denver Meeting of the American Medical Association.—The committee of arrangements announces that preparations for the coming meeting are well advanced. A large number of prominent men have signified their intention to be present and read papers, and an excellent scientific programme is assured. The indications all point to a large and successful meeting. The entertainment of members and their families is being planned on an elaborate scale, and the committee promises all who may come a most enjoyable time. Local excursions are being arranged to take place after the meeting, that all may have ample opportunity of visiting various points of interest in the State and seeing the best scenery of the Rocky Mountains. The committee confidently expects to obtain a one-half rate and thirty-day limit for the round trip on roads west of Chicago and St. Louis, and reduced rates on Eastern roads.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending March 26, 1898. Surgeon L. G. Heneberger detached from the *Maine* and ordered home to await orders: Surgeon S. H. Griffith detached from the Museum of Hygiene, Washington, and ordered to the *Mayflower*.

Lectures on Climatology.—Dr. S. E. Solly, of Colorado Springs, has consented to deliver a special course of lectures on climatology, in the New York Post-Graduate Medical School and Hospital. The lectures will be on April 25th, 26th, 29th, May 2d, 4th, 6th, at 5 P.M. Admission will be by ticket only. Members of the profession not specially invited may secure tickets, without charge, on application, either personally or by note, to the superintendent, in the office of the school.

The Cincinnati Academy of Medicine. — At the annual meeting of this society, held March 7th, the following members were elected as officers for the ensuing year: *President*, Dr. Louis Schwab: *Vice-Presidents*, Drs. J. C. Oliver and Estella Riley; *Treasurer*, Dr. S. E. Allen; *Secretary*, Dr. W. H. Crane; *Trustees*, Drs. N. P. Dandridge, J. A. Murphy, and J. T. Whittaker.

Congress for the Study of Tuberculosis.—The fourth congress for the study of human and animal tuberculosis will be held in Paris during the week beginning July 27, 1898. The questions proposed for discussion are: (1) "Sanatoria as a Means of Prophylaxis and Treatment of Tuberculosis;" (2) "Serums and Antitoxins in the Treatment of Tuberculosis:" (3) "The *x*-Rays in the Diagnosis of Tuberculosis:" (4) "The *x*-Rays in the Treatment of Tuberculosis;" (5) "The Prophylaxis of Animal Tuberculosis:" (6) "The Prophylaxis of Human Tuberculosis by Disinfection of Places Inhabited by Tuberculous Patients;" (7) "The Diffusion of Tuberculosis in the Army and its Prophylaxis." Other titles of questions proposed for discussion are: "The Semeiological and Prognostic Value of Tachycardia in Pulmonary Tuberculosis:" "Tuberculous Infection by Milk and the Means of Avoiding it;" "The Modifications in Form of the Tubercle Bacilli and their Pathological Significance:" and "The Organic, Cellular, and Humoral Conditions which Constitute the Tuberculous Soil, and which Predispose to Tuberculosis."

Reviews and Notices.

DISEASES OF WOMEN. A Clinical Guide to their Diagnosis and Treatment. By GEORGE ERNEST HERMAN, M.B. Lond., F.R.C.P., Obstetric Physician to and Lecturer in Midwifery at the London Hospital, Consulting Physician-Accoucheur to the Lower Hamlets Dispensary, etc. With 252 Illustrations. Pp. xvi.+886. New York: William Wood and Company. 1898.

THE unusually brief and modest preface of this attractive volume concludes with this sentence, which forms the keynote to the whole: "I may plead that I have one qualification for writing such a book, not always possessed by the authors of text-books, namely, clinical experience."

The arrangement of the subject matter is not only novel but most helpful to the student. It is divided into eleven parts, as follows: Part I. is introductory, dealing with neurasthenia, hysteria, headache, and pelvic and abdominal pain. Part II., on "Chronic Pelvic Pain," includes chapters on ovarian pain, uterine pain, and uterine displacements. Part III. treats of pelvic inflammations, Part IV. of internal hemorrhage, and Part V. of uterine hemorrhage from all causes. Five chapters are devoted to leucorrhœa and its causes and ten to the disorders of menstruation. Part X. (six chapters) treats of urinary disorders, while the concluding section includes nine chapters on abdominal tumors.

The author discusses in turn the principal symptoms of pelvic trouble—pain, hemorrhage, and disorders of menstruation—and after thoroughly analyzing the causes of each proceeds to describe the local condition which gives rise to it. This arrangement presents many advantages and invests the study of gynæcology with a new interest. For example, the familiar symptom, backache, has never been treated more rationally than in Chapter V. Chronic ovarian pain is handled most ably, the remarks on "So-Called Chronic Oöphoritis" being in every sense sound and conservative. Notwithstanding that the pathological views of the author are in certain instances at variance with generally accepted opinions, from a clinical standpoint he is safe and eminently practical.

A strict adherence to his plan leads, necessarily, at times to repetition, but this is a minor fault.

We can hardly approve of some of his dogmatic statements in the chapters on displacements and pelvic inflammation, though his opinions are always well supported. He does not fear, on this and other subjects, to differ from high authorities.

The style is forcible and epigrammatic. Operations are described briefly, but with a clearness and attention to practical details rarely met with even in monographs on operative gynæcology. The illustrations are most attractive, and the type and binding above reproach. Taken as a whole, we have no hesitation in bestowing our warm commendation upon this recent addition to special literature, believing it to be in many respects one of the most honest and original works on gynæcology that have yet appeared. To the student it will be simply invaluable.

TEXT-BOOK OF NERVOUS DISEASES. Being a Compendium for the Use of Students and Practitioners of Medicine. By CHARLES L. DANA, A.M., M.D., Professor of Nervous and Mental Diseases in Bellevue Hospital Medical College, Visiting Physician to Bellevue Hospital, Neurologist to the Montefiore Home, ex-President of the American Neurological Association, etc. Fourth Edition, Revised and Enlarged. With 246 Illustrations. New York: William Wood and Company. 1897.

As the merit of the former editions of Dr. Dana's work has obtained for it a well-deserved recognition as a standard text-book, it is of interest to note here those additions and rearrangements which the author has made to keep the book abreast of the rapid advances in work along neurological lines. The recasting of the chapters on the general considerations of the structure and relations of the neuron presents that part of the work in a new and philosophical manner. In the chapters upon the diseases of the cranial nerves, etc., the classification has been judiciously modified so as to present in distinct chapters the motor neuroses of the cranial nerves, the motor neuroses of the spinal nerves, and the sensory neuroses of the cerebro-spinal nerves. The chapter on locomotor ataxia has been rewritten, to accord with the teachings of the past few years, and some valuable illustrations have been added. The group of diseases allied to spastic spinal paralysis, the combined scleroses and the hereditary paralyses, has been definitely set forth and its perplexing synonymy put in a clear light. A number of new subchapters is here added, treating of glosso-labial paralysis, asthenic bulbar paralysis, etc. The rapid increase in knowledge relative to the muscular atrophies and the muscular dystrophies is briefly and well epitomized in the chapters upon these diseases. The chapter on "Neurasthenia" is a most scholarly discussion of this condition and presents the subject fully and clearly. Under trophic and vasomotor neuroses a number of new paragraphs has been added, among which are included the subjects of myxœdema and cretinism.

The fine quality of book work in this edition cannot but impress the reader. The typography and spacing of the letters as well as the heavy paper and broad margins lend an ease to the student which he seldom finds in reading a text-book. Many new illustrations have been added to replace former cuts, as well as illustrate new points. All are suggestive and well reproduced, and add to the interest and value of the reading-matter. In short, Dr. Dana's already well-known work on nervous diseases is as fine an example of the modern text-book as can be found, thoroughly scientific and up to date, modern in its treatment, clear and succinct in its diction, and a fine specimen of the publisher's art.

ARCHIVES OF THE ROENTGEN RAY. Edited by W. S. HEDLEY, M.D., and SYDNEY ROWLAND, M.A. London: The Rebman Publishing Company, Limited. Philadelphia: W. B. Saunders. 1897.

VOLUME II. of what was formerly called the "Archives of Skiagraphy" has appeared. Besides the usual number of skiagraphs of rare and interesting conditions, including the entire skeleton of a woman taken at one exposure by Morton, there is an article on the nature of the rays, by Silvanus P. Thompson, and other *x*-ray literature, aside from the explanatory text for the plates.

MEDICAL REPORTS. From the Poliklinik for Diseases of Children of Privatdocent Dr. Huho Neumann in Berlin. 1897.

THE first announcement from this institution has just been received. It describes in detail the various departments, the laboratories, dissecting-room, surgical and emergency wards, infectious and isolating rooms, etc.

The poliklinik is modelled on a very unique plan. First, no adults are treated. Second, there are a children's (*a*) dental, (*b*) laryngological, (*c*) eye and ear, (*d*) orthopædic, (*e*) surgical, (*f*) medical (heart, lungs, gastric), (*g*) dermatological, (*h*) isolating wards for infectious cases. Third, only a few cases are retained and no infectious child is admitted.

The location of the building is in the Blumenstrasse, No. 78, in the most densely populated district of the city and Dr. Neumann, hopes to do great good for this reason. There are articles on "Clinical Diagnosis of Scrofulosis" and "Scleroderma," by Dr. Neumann; "The Etiology of Acute Summer Diarrhœa," by Dr. Hermann Cohn; on "Infantile Tabes and Hereditary Syphilis," by Dr. H. Maass and Dr. S. Kalischer; on "Congenital Defects of the Eyes," by Dr. Ginsberg; and on "Acute Middle-Ear Disease," by Dr. Teichman and Dr. Alfred Gebart.

The scientific contributions in this first number deserve especial mention, and will repay all who read them. The director of this poliklinik is too well known to need introduction, and is entitled to great credit for the most thorough manner in which this work has been commenced. It will serve as a good model for all future pædiatric institutions. The whole series of articles is reprinted *in extenso* in Professor Baginsky's *Archiv für Kinderheilkunde*, which speaks for itself.

LECTURES ON THE MALARIAL FEVERS. By WILLIAM SYDNEY THAYER, M.D., Associate Professor of Medicine in the Johns Hopkins University. New York: D. Appleton & Co. 1897.

THE author of this volume has made the attempt to place before the reader a summary of what is at present known and alleged to be known on the widely interesting subject of malaria. Presented in the form of lectures, the topics dis-

cussed are fairly complete, and the reader is never left in doubt concerning the author's position in regard to most points in connection with paludal infection. The somewhat obtrusive tendency to dogmatic assertion appears pardonable when we remember that these lectures were primarily intended for the instruction of students.

The chapters devoted to laboratory methods and pathology are far more satisfactory than those relating to clinical matters, showing that the author is more at home in his study than at the bedside of *bona-fide* patients. In some directions Dr. Thayer goes too far. Thus, we cannot accept his sweeping statements in regard to the non-existence of "malarial pneumonia," "typho-malarial" fever, etc. It is utterly absurd, for example, for one appointed to teach medicine to young students, to assert that "with our modern methods of diagnosis, and the recent advances in our knowledge of the intimate nature of both typhoid and malarial fevers, we now know that no such condition exists." Competent observers, at least as well qualified to judge as Dr. Thayer, have positively demonstrated the actual occurrence of these mixed infections, and it is merely gratuitous assumption on the author's part to set aside well-established facts.

The chapters on treatment are the least satisfactory part of the volume, showing bedside inexperience and a lack of therapeutic resource which actual patients would not be disposed to tolerate. The charts and colored plates help to elucidate the text of these lectures, which, with added clinical experience and greater tolerance on the part of the author, may readily be made fairly representative of the present state of our knowledge concerning malaria.

TRANSACTIONS OF THE MEDICAL SOCIETY OF NEW JERSEY. 1897.

THIS year's report comes as a bound volume of three hundred and forty-five pages. Besides the president's address there are essays by George Bayles, "The Value of Antitoxin;" by L. F. Bishop, "The Treatment of Pneumonia;" by T. R. Chambers "The Progress of Ophthalmology and Otology;" and a "Report on Surgery" by Charles Young, etc.

CONSTIPATION IN ADULTS AND CHILDREN. With Special Reference to Habitual Constipation and its Most Successful Treatment by the Mechanical Methods. By H. ILLOWAY, M.D., formerly Professor of the Diseases of Children, Cincinnati College of Medicine and Surgery, etc. New York. The Macmillan Company. 1897.

ALMOST five hundred pages of constipation seems a good deal for what is really only a single chapter of alimentary symptomatology. Nevertheless, when one reflects that almost all Americans are supposed to be more or less constipated, excepting that hopeless minority which suffers from chronic diarrhœa, one is tempted to forgive the author of so profound and elaborate an exposition of what slow stools really mean. After a careful examination of Dr. Illoway's beautifully illustrated treatise, the reader will be inclined to exclaim: "There is more in defecation than is dreamt of by those who have not been closely associated with expert fæcologists." Certainly the straight path of the rectal specialist seems a small field of activity when thus contrasted with the never-ending tortuousness of uncomfortably constipated sigmoid flexures. The coilful cooings of sluggish colons, too full for spontaneous stalsis, are alluringly set forth by the author.

As we continue our examination we discover that Dr. Illoway is equally familiar with all branches of the long tract which constitutes his theme. Whether we look into the open main road of intestinal construction, or follow him into the more modest nooks given over to jejunal enjoyments; whether we peer into the numerous bends and bypaths of iliac fields, or finally penetrate to the uttermost recesses of occult cæcal impaction, we will always find that the author has been there before us, and that he has left us no alternative but to admire his indefatigable zeal and learning. Nor are we at all surprised to be confronted with so many kinds of constipation. Indeed, we have looked in vain for some particular variety which might have escaped the author's deep insight.

In the matter of treatment also, Dr. Illoway is not disposed to overlook a single measure which might aid in expediting dangerously delayed stools. Altogether, from whatever aspect we may regard this volume, we must credit the author with having produced a satisfactory treatise on a subject which is of daily concern to all of us, and which no practitioner can well afford to neglect.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science by Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D. In Twenty Volumes. Vol. XIII. Infectious Diseases. New York. William Wood and Company. 1898.

ALTHOUGH the number thirteen is usually supposed to carry with it certain elements of ill-fortune, we can discover nothing about the present volume to warrant a supposition of misfortune attending its production, unless it be in the recent and untimely death of one of its contributors—Mr. Ernest Hart. In his article on "Water-Borne Diseases" he was assisted by Dr. Solomon C. Smith, also of London, and together they have made a very interesting study of water, not only as a medium in which pathogenic organisms may grow, but also as the vehicle of distribution of poisons both of organic and inorganic substances. Much of the space is naturally devoted to cholera, typhoid, and malaria. The first chapter deals with ptomains, toxins, and leucomains, and has been very carefully prepared by Victor C. Vaughan, of Ann Arbor, so well known for his labors in this particular field. An important feature of the chapter is a subdivision in which are considered the poisons of the specific infectious diseases. This is followed by a still longer chapter contributed by Harvard's professor of bacteriology, Harold C. Ernst, on infection and immunity. By "infection" is understood "the condition produced by the entrance and multiplication of pathogenic micro-organisms within the body." When we consider all the possibilities of simple and mixed infections, and the broad subject of acquired immunity, we can realize the task of stating the whole case, as it appears to the scientist to-day, in the allotted number of pages. Dawson Williams, of London, physician to the East London Hospital for Children, has given ten pages to the "duration of the period of incubation and infectiousness in acute specific diseases," and very appropriately following this chapter is one on small-pox by John William Moore, of Dublin, who, among many other things, is consulting physician to the Fever Hospital. The excellence of the article shows that the editor has chosen well. "Vaccina" is the title of a chapter by Professor Brouardel, of Paris, in which vaccination in its many phases has been considered.

Not the least interesting chapter for its size is that on "Mumps," by Jules Comby, the well-known French writer on children's diseases. For one who has not kept up with the literature of parotitis during recent years, there will be found in this report on the subject much that is striking and important.

Taken as a whole, the volume is as advanced and scientific as any of the series we have had an opportunity to read, and maintains the high standard originally promised by the editor.

THE RETROSPECT OF MEDICINE. A Half-Yearly Journal. Edited by JAMES BRAITHWAITE, M.D. Lond., Obstetric Physician and Surgeon to the Leeds General Infirmary, etc., assisted by E. F. Trevelyan, M.D. Lond., B.Sc., M.R.C.P., Assistant Physician to the Leeds General Infirmary, etc. Vol. CXVI. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited. 1898.

THIS issue, covering the literature from July to December, fairly well represents the progress made in various departments. The bulk of material, however, is drawn from English and American sources, and reflects only imperfectly the vast amount of work done in surgery and special branches in Germany, France, and Russia. It is an ever-welcome and highly useful publication.

RINGWORM AND ALOPECIA AREATA. Their Pathology, Diagnosis, and Treatment. By H. ALDERSMITH, M.B. Lond., F.R.C.S.; Medical Officer, Christ's Hospital, London. Fourth Edition, Enlarged and Rewritten, with New Illustrations. London: H. K. Lewis. 1897.

ALTHOUGH called a fourth edition, the work as it is here presented may be considered a new book.

Recent French investigations have exercised an undoubted influence, and Sabouraud's varieties of tinea have in the main been accepted after corroborative investigation.

Seven beautiful plates illustrate the small and large spored

tineas, under various amplitudes and demonstrating different phases of development.

Much space is devoted to treatment, and the subject has been very conveniently subdivided.

The croton-oil treatment and needling, advocated many years ago by the author, has received particular attention, and the question of medical certificates has been dealt with in a manner both timely and praiseworthy and deserving of consideration because of the long experience upon which opinions are based. An interesting chapter on alopecia closes the volume.

Lexique-Formulaire des Nouveautés Médicales et Biologiques. Par le Prof. Paul Lefert. Paris: Librairie J. B. Baillière et Fils. 1898.

This little duodecimo of three hundred and fifty pages, including a "répertoire," deals not only with new remedies but with new diseases, new syndromes, and new operations.

There are also some matters touched upon which cannot be counted as novelties.

It offers an easy means of keeping up with the times.

Association Française d'Urologie, Paris, 1897. M. le Dr. Desnos, Secrétaire-Général. Paris: Octave Doin, Editeur. 1898.

This is a report of the transactions, memoirs, and discussions of the society in its second session.

There are sixty-five woodcuts scattered through four hundred and eighty pages of text, comprising many valuable papers and reports.

An excellent feature is the analytic table of contents.

Louis Kuhne's Facial Diagnosis. Illustrated. A Free and Abridged Translation with Notes. By August F. Reinhold, M.A., Manager of the Reinhold Institute of Water Cure of New York City. Published by A. F. Reinhold, New York City. 1897.

This is not a medical work, but one written by a man who opposes treatment by drugs and diagnosis by recognized methods: the author says his method will appeal more particularly to women, and, in this, we most fully agree. There are many pictures of people with "encumbraes," all however curable by water, as applied at the translator's institute.

Transactions of the Colorado State Medical Society. Twenty-Seventh Annual Convention, Denver, June, 1897.

Bound in conformity to the volumes of previous years and with a frontispiece portrait of President Levy, the report covers four hundred and seventy pages and embraces a large number of papers, of which many are above the average of excellence.

The publication committee, headed by Dr. H. B. Whitney, deserves a word of praise for the manner in which its work has been done.

Transactions of the Chicago Pathological Society. From December, 1895, to April, 1897. Vol. XI.

The salient points in the various sessions of the year have been touched upon and many papers are given *in extenso* or in *résumé*.

Much of the three hundred and twenty-eight pages is given up to the description of cases presented and discussion thereon.

Transactions of the British Orthopædic Society. Vol. XI. Session of 1896. Published by the Society. London: John Bale, Sons & Danielsson, Limited. 1897.

This is a very brief report, covering but fifty pages. It contains, however, interesting papers on congenital torticollis, congenital dislocation of the hips, recrudescent rickets, and early diagnosis of affections of the spinal column.

Die bacteriologische Technik. Von Dr. Bruno Schürmayer. Leipzig: Druck und Verlag von C. G. Naumann.

This compact handbook (duodecimo) is evidently intended for use in the laboratory. It is divided into two parts: the first treating of the bacteriological technique, the second of the pathogenic bacteria. The part on technique is very complete, and for such a small, unpretentious volume is very much up to date in methods of preparation of media and staining and culture. It is liberally illustrated, with an index of its own. The second part, on the pathogenic bacteria, is also quite exhaustive and contains much information in small compass. Each section, such as, we will say, that on the bacillus typhosus, is accompanied by an exhaustive summary of literature which will be found invaluable. We feel that this small work is a useful addition to our laboratory manuals.

Studies in the Psychology of Sex. Vol. I. Sexual Inversion. By Havelock Ellis. London: The University Press. 1897.

The author prefaces his work with the declaration that a resolve slowly grew up within him that "one main part of my life work should be to make clear the problems of sex." This elucidation is one of such magnitude that the reader is not surprised to see farther along that, instead of settling those great problems, the author is "quite content" to do "little more than state them." One is reminded by the general scope and the cases recorded of the well-known German works on the same subject, but the facts are new and presented in a somewhat new light. The school (especially in England) is looked upon as the great breeding-place of artificial homo-sexuality, and in a large proportion of instances there is thought to be little of the congenital element.

The medical, medico-legal, and social aspects are all duly considered in a scientific spirit, free from prudery or morbid sentimentality. Among the appendices is a chapter on homosexuality among tramps, by Josiah Flynt, well known by his writings in American magazines.

Street Cleaning and the Disposal of a City's Wastes. Methods and Results and the Effect upon Public Health, Public Morals, and Municipal Prosperity. By George E. Waring, Jr., Commissioner of Street Cleaning in the City of New York. New York: Doubleday & McClure Company. 1898.

This is a most interesting account by the former street-cleaning commissioner of the way the streets of this city were cleaned under his administration. The entire work is here explained—street sweeping, carting, removal of snow, and the removal and final disposition of garbage, street sweepings and ashes, and paper and rubbish. The story told is instructive, for it illustrates what can be done for a community by taking the administration of its affairs away from the domination of professional politicians and placing it in the hands of competent men who are free from the smirch of "patronage."

Handbook of Materia Medica, Pharmacy, and Therapeutics. Including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Practical Pharmacy, and Minute Directions for Prescription Writing. By Samuel O. L. Potter, A.M., M.D., M.R.C.P. Lond.; Professor of the Principles and Practice of Medicine and Clinical Medicine in the College of Physicians and Surgeons of San Francisco; Medical Superintendent of St. Mark's Hospital, etc. Sixth Edition, Fully Revised and Greatly Enlarged. Philadelphia: P. Blakiston, Son & Co. 1897.

We have no desire to detract in any way from the Medical Record's originally expressed opinion of Dr. Potter's work. The unusually strong terms employed on former occasions have proved warrantable by the fact of this sixth edition appearing. The claim that the work has been fully revised is a just one. Much labor must have been spent in perfecting the various departments and bringing them abreast of the times. When you are trying to find out something about a drug and what it is supposed to do, Dr. Potter's handbook is a good source of information to which one can confidently turn.

La Diphthérie et la Sérum Thérapie. Études Cliniques Faites au Pavillon Bretonneau. Par le Dr. G. Variot, Médecin de l'Hôpital Trousseau, avec la collaboration pour la partie bactériologique de M. le Dr. Tollemer. Paris: A. Maloine, Editeur. 1898.

This very timely work is by two well-qualified observers, Dr. Tollemer being the chief of the laboratory for diphtheria at the Trousseau hospital for sick children, and Dr. Variot having been during 1895 and 1896 in charge of the special diphtheria service. They have produced a volume of five hun-

dred and sixty pages, containing twenty-eight figures in the text and one colored plate.

The whole question of treatment by serums is gone over and considerable attention has been paid to intubation, a number of pictures being introduced to explain matters of technique. The technique of clinical bacteriology has been gone into extensively and new observations upon modifications brought about by the serum of Behring will be noted. Observations extending to upward of three thousand cases, treated with the result of bringing down the mortality from fifty per cent. to fourteen per cent., will prove interesting to all who have to do with pædiatric practice.

A Practical Treatise on Diseases of the Skin. Fourth and Revised Edition. By James Nevins Hyde, A.M., M.D., Professor of Skin and Venereal Diseases, Rush Medical College, Chicago; Dermatologist to the Presbyterian, Augustana, and Michael Reese Hospitals, etc.; and Frank H. Montgomery, M.D., Lecturer on Dermatology and Genito-Urinary Diseases and Chief Assistant to the Clinic for Skin and Venereal Diseases, Rush Medical College, Chicago, etc. Philadelphia and New York: Lea Brothers & Co. 1897.

Dr. Hyde's work has been well received. It is illustrated with one hundred and ten engravings and twelve plates in colors and monochrome. The present edition is more pleasing to the eye, and attentive reading of the text shows many alterations and improvements. Certain unnecessary paragraphs and matter have been omitted to make room for a discussion of newer facts pertaining to important affections. Thus the size of the volume has not been materially increased by the elaboration.

A Practical Treatise on Appendicitis. Prepared Especially for the Use of Students and General Practitioners. By Howard Crutchers, M.D., Professor of Surgical Anatomy and the Principles of Surgery in the Dunham Medical College, Chicago, etc. Illustrated. Chicago: Hahnemann Publishing Company. 1897.

For those whose experience in this rapidly increasing affection is still limited the author presents one hundred and thirty-two pages of instructive information and advice. Readers of the Medical Record have already had an opportunity of learning the author's views bearing upon the subject of appendicitis, and many will undoubtedly be pleased to learn further of them.

Proceedings of the Seventh Annual Meeting of the Association of Military Surgeons of the United States. Held at Columbus, Ohio, May 25, 26, and 27, 1897. Edited by James E. Pilcher, M.D., Captain in the Medical Department of the United States Army, Secretary and Editor of the Association.

This handsomely bound volume of over seven hundred pages contains many interesting papers, chiefly upon topics of military surgical interest. A frontispiece represents a grouping of the members in uniform. Besides this there are many well-executed pictures in the text and in the appendix, the latter from scenes about the Columbus barracks, etc. The paper and print are excellent, and the report as a whole calls for a word of praise for the editor.

Transactions of the Clinical Society of London. London: Longmans, Green & Co. 1897.

This is the thirteenth edition of this society's proceedings. It is interesting from the brief description of numerous cases, some of them rare ones.

The Physician's Visiting List for 1898. Philadelphia: P. Blakiston, Son & Co.

This is the forty-seventh year of this firm's (formerly Lindsay & Blakiston) publication. Besides the blank pages, arranged as usual, there are a dose table including the newer remedies; "Asphyxia and Apnœa," from Potter's work; and a table of comparison of thermometers from Gould's Dictionary.

Exercise in the Morning.—Early morning exercise is denounced nowadays by the majority of hygienic teachers. At that time, they say, vitality is at its lowest ebb and needs the stimulation of food.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 17, 1898.

Edward G. Janeway, M.D., President.

Dr. Seguin's Bequest to the Academy. The will of the late Dr. E. C. Seguin bequeaths to the Academy of Medicine a valuable collection of pamphlets on the nervous system, together with all of his books directly relating to pathology and etiology of diseases of the nervous system; also an oil painting of his father, Dr. Seguin; also an autograph letter from Pope Pius IX., regarding his father's work for backward and imbecile children; also a bronze medallion of Charcot, given him by Charcot himself; also a large photograph of Brown-Séquard, the only large picture of him now extant.

The New York Hospital Library. It was announced that the Society of the New York Hospital had donated its entire library of twenty-three thousand volumes to the academy, and that as soon as these books could be arranged and properly catalogued they would be placed at the disposal of the members. This munificent gift will greatly enlarge the circulating portion of the library.

The Ultimate Results of Thyroid Treatment in Sporadic Cretinism.—Dr. Henry Koplik read a paper on this subject. The meeting was in charge of the section on pædiatrics. Dr. Koplik said that the disease in question was identical in its symptomatology in all countries. In this country alone Osler had collected fifty-eight cases of cretinism; of these subjects twelve were born here. In no part of this land did one meet with endemic cretinism. Before the introduction of the thyroid treatment, the cretins were banished from society and were treated very much as lepers. To-day, thyroid therapy made it possible to care for these unfortunates within the family circle. After three weeks of treatment the infant would have lost the prominent features of its disorder. Three great classes should be sharply distinguished, viz., those coming under treatment in infancy, in childhood, and in adolescence or adult life. The most satisfactory results were naturally obtained in the first class. The three cases of this class that he had treated had exhibited wonderful improvement. In the second class the diagnosis was made when the patient had fully developed into a cretin idiot. The ages in this group ranged from fifteen months to four years. In fifty-two cases collected in Great Britain, more than half the patients presented symptoms of the disease before eighteen months of age. He had treated two cases of this class, but with results which were not entirely satisfactory. Of Osler's fifty-eight cases, eighteen were in children below the age of five years, and of these eighteen only five were considered to be perfectly normal after treatment. The other thirteen showed a marked and immediate improvement, especially in the myxœdematous symptoms. Of Osler's series, forty patients were over five years old, the oldest being between of sixty and seventy years. Thirteen were put on the thyroid treatment, and improved to varying degrees, yet in not one instance did the record indicate that the person had been restored to the normal. In children of from five to sixteen years the myxœdematous symptoms disappeared, but they were childish, possessed a limited vocabulary, and walked with an uncertain gait. If the cases were treated early, before the disease had stultified the brain and nervous system, the results reached the greatest perfection; hence the importance of making

an early diagnosis. In the first class the results seemed at present to be the most promising. In the second class—those under five years—the results had been variable. The immediate effect of the thyroid treatment was marvellous, as far as regarded the prompt transformation in the physique and features of all cretins. The older the cretin, the more lacking would be the essentials for making a perfectly normal individual. It had been recently suggested to give thyroid to pregnant women who had borne cretins, but it had been shown that cretinism had supervened years after birth. He recalled one woman who had borne a normal child after having given birth to a cretin.

A series of lantern slides was then exhibited to illustrate the peculiar features of cretins and the results of thyroid treatment.

Dr. A. Jacobi said that he had found that, as a rule, when the treatment was interrupted, there was a speedy relapse. If the treatment could be kept up indefinitely, there would be marked improvement, but not a cure. So far no satisfactory substitute for the thyroid had been found. Last year Fraenkel had announced that thyro-antitoxin relieved the symptoms, but it was found on further investigation that only some of the symptoms were ameliorated, chiefly the convulsive ones.

Future Hope Lies in Thyroid Transplantation.—The hope of permanent cure, he believed, was to be found only in transplantation of the thyroid. This had been tried some years ago. One of the first of these cases was quite successful, as far as it went. The first transplantation was made in January, 1889, in a cretin girl who had epilepsy. The thyroid was transplanted into the peritoneum. She became very much better, and remained so for a few months, but then relapsed. Did this implanted thyroid act by its vascular connection, or because thyroid was present in the body of that girl? He did not believe a permanent cure could be effected unless a vascular connection could be established. It would seem that there must have been a vascular connection in this case in order to cause improvement in this girl for a period of months.

Some Cases are Brachycephalous.—In a certain number of cases it was not the degenerated thyroid only which was the cause of the condition. About one-third of the cretins that he had seen showed the peculiar symptoms of brachycephalism. The base of the cranium and correspondingly the base of the brain were abnormally short. More than forty years ago it had been shown that this shortness was because the junction between the sphenoid and the occipital bones became ossified at a very early stage. As this condition could not be relieved, such patients must necessarily continue to suffer from the symptoms dependent upon this defect. A few of the cases exhibited this evening appeared to him to be due to brachycephalism. This was often due to rachitis. The eburnation of the bone which usually took place in the third year occurred in these infants before birth, and before the other bones had become ossified. The younger the infant, the more reason there was to expect a good effect from the remedy.

Persistence of the Thymus.—Dr. Jacobi said that in a number of cases he had observed one peculiarity, *i.e.*, the large size of the thymus gland. There must be some anatomical or physiological connection between degeneration and atrophy of the thyroid gland and the large size and persistence of the thymus gland. He had seen cretins of eight or ten years who had a very large thymus. The large majority of cases in which he had observed persistence and enlargement of the thymus had been cases of cretinism.

Children's Tolerance of Thyroid.—Dr. George W. Crary said that most observers who had had cretin children under their care had been disappointed with the results of the thyroid treatment. If the child had been developing for some time along the false route of cretinism, some time must elapse before developmental changes could be noted as a result of treatment with thyroid, although the myxœdematous symptoms promptly responded. It should be remembered also that all cretins of the same age were not in the same condition—in other words, there were various degrees of cretinism. Another point worthy of note was that infants showed a tolerance to increasing doses of the thyroid which was out of all proportion to their increasing age.

Best Results from the Gland Itself.—He had also been struck with the great differences observed in the preparations of different though reputable manufacturers. He did not think any of the preparations on the market contained all the elements needed. This was shown by the results obtained in children. He had obtained far better results from using the actual gland than from any of the preparations.

The Chief Obstacle to Treatment.—The fever and restlessness and insomnia induced by the thyroid he had found the chief obstacle to carrying out the treatment. He was sceptical regarding softening of the bones and the occurrence of spinal curvature being the result of thyroid treatment, as some had claimed. Their bones were soft because they were cretins and not because of the thyroid treatment. The administration of thyroid to pregnant women to prevent the birth of cretins seemed to him utterly illogical. He could not agree with Dr. Jacobi that there was much to be expected from transplantation of the thyroid, for it had been demonstrated experimentally that the thyroid disappeared. When the thyroid had been transplanted into the peritoneal cavity with its capsule, the absorption was so slow that improvement might very easily extend over two or three months.

Hydrocephalus and Cretinism Confounded.—Dr. E. D. Fisher also thought that the great difficulty in continuing treatment was the fever and restlessness produced. He recalled one child who brightened up under the use of the thyroid, but showed a mental irritability rather than a true improvement in mentality. A very common mistake in diagnosis was to confound hydrocephalus and cretinism; yet in the former the head was large, while in the latter, although the head was large, the face appeared rather small. The short, stumpy appearance of the cretin was quite characteristic. The thin skin, the blue veins, and the generally refined appearance of the face in hydrocephalus were in striking contrast with the myxœdematous skin and the brutish appearance of the cretin. He had never had a case in which he could say that there had been a perfect restoration to the normal.

Dr. W. M. Leszynsky said that his experience with the thyroid treatment had been, on the whole, unsatisfactory. In one or two advanced cases the only improvement noted was in the myxœdema.

The Fever and Restlessness Due to Cadaveric Toxins.—Dr. Koplik said that it was true that some of his cases were of the brachycephalic type. He had also found that children often became quickly tolerant to the use of the thyroid gland. It had been ascertained by one physiologist recently that the fever and restlessness referred to were not due to the thyroid gland itself, but to toxic substances which developed in the gland, as a result of decomposition after it had been taken from the animal. It would seem, therefore, that Dr. Crary's plan of giving the fresh gland was the better one.

National Bureau of Health.—In response to the resolutions on this subject recently adopted and forwarded by the academy to the chamber of commerce, that body sent a communication, stating that it had unanimously adopted the following resolutions:

"*Resolved*, That this chamber hereby records its hearty approval of the principles contained in senate bill No. 3,433, introduced by Senator Spooner in the senate of the United States, entitled, 'A bill to establish a commission of public health, and define its duties.'

"*Resolved*, That senate bill No. 2,680, introduced by Senator Caffrey, and bill of the house of representatives No. 4,663, introduced in the house by Mr. Hepburn, in the opinion of this chamber would, if passed, defeat the efforts that have been made in the past for the establishment of a much-needed national board of health; and

"*Resolved*, That copies of these resolutions be sent to each member of the senate and to each member of the house of representatives."

SECTION ON GENERAL MEDICINE.

Stated Meeting, March 15, 1898.

LOUIS FAUGÈRES BISHOP, M.D., CHAIRMAN.

Double-Current Irrigation.—DR. ROBERT COLEMAN KEMP gave a demonstration of the method of using double-current irrigation. He said that he had found that by elevation of the hips as good results could be obtained with short tubes as with the long colon tube. The advantages claimed were: (1) the quantity of fluid in the bowel was absolutely under control; (2) the temperature of the fluid could be kept uniform; (3) a clean solution continually replaced the foul solution—a matter of importance in cases of typhoid fever or of dysentery; (4) tympanites was rapidly relieved by such irrigation, for the water as it passed out carried the gas with it; and (5) it permitted using a large quantity of fluid and utilizing a large surface for absorption, as was required in uræmia and shock. It was convenient to place the patient in the Sims position, with the hips considerably raised.

DR. BEVERLEY ROBINSON asked what was the advantage of the method over the use of a single tube in cases in which it was desired to have a quantity of saline solution absorbed. He also asked if there was any method of determining the height to which the fluid had gone, aside from the sensations of the patient and the results of percussion.

DR. KEMP replied that it was a simple matter to use a graduated irrigator and a graduated jar for receiving the outflowing fluid, and thus determine the quantity of fluid in the bowel. If a high enema was given with a single tube, it cooled much more rapidly than when the double tube was used. Then, again, in many cases of uræmia there was incontinence of fæces, and without the double tube it was very difficult to have a sufficient quantity of fluid retained in the bowel long enough to be of benefit. The method with the double tube was also very much more efficacious in removing accumulations of gas. It acted on the principle of the Sprengel air-pump, the air being removed in a series of small bubbles with the circulating fluid. This was the theory of its action, and it was very easy to demonstrate this clinically.

DR. ROBINSON spoke of some remarkably good effects that he had observed from injecting saline fluid into the bowel in desperate cases of typhoid fever. It probably acted by diluting the poison, but its salutary action could not be doubted. He would like to know if in such cases the absorption of the fluid would be greater from the double-current method than from the use of the single rectal tube.

DR. KEMP said that he had found by laboratory experiments that the absorption from the intestine did not manifest itself until the hot saline solution had been flowing for twenty minutes. This prolonged action could not be well secured by the single tube.

Rheumatoid Arthritis.—DR. C. C. RANSOM read a paper with this title. He said the term rheumatoid arthritis was open to a number of objections, not the least of which was the suggestion that this condition should be treated as a rheumatic disorder. He, therefore, greatly preferred the term arthritis deformans. Osteo-arthritis he looked upon as a condition of the joints which might be present in gout, rheumatism, or arthritis deformans—in other words, it was not a disease *sui generis*. Sydenham believed arthritis deformans to be a form of rheumatism, and many other well-known clinicians had held the same opinion. Hutchinson believed it to be made up of chronic rheumatism and gout, and others were of the opinion that the affection was the result of gout, and that the trophic changes in the joints were brought about by an excess of uric acid circulating in the blood. The most recent theory, and the one which seemed to him best to account for the phenomena of the disease, was that which asserts arthritis deformans to be due to a species of bacteria, which by natural selection first attack the joints, and afterward by the toxins give rise to the general feature of the disease. Certain special micro-organisms had been found constantly in the synovial fluid in these cases. This organism was a minute bacillus which exhibited marked polar staining. By this theory all the curious and hitherto unexplained phenomena could be easily accounted for. According to his own experience, heredity had not been a prominent etiological factor. Tuberculosis and scrofula had been regarded as frequent antecedents, but in the five cases that he now had under observation there was no history of rheumatism, gout, or tuberculosis. As a rule, the onset was very insidious, there being occasional joint pains for months, with more or less constitutional disturbance and a feeling of general malaise. There were also a diminution in general weight and a peculiar atrophy of certain sets of muscles. Albuminuria was exceedingly rare, and the urine showed no excess of uric acid. Profound anæmia was observed early. Although there might be hæmic murmurs heard about the heart, there was no associated organic cardiac disease. In the beginning the joints assumed a typical spindle-shaped deformity. Very soon structural changes took place.

Treatment.—The treatment of arthritis deformans had very little to offer. The aim should be to check the progress of the disease as far as possible and to limit the disease to the joints already affected. The remedies used in the treatment of rheumatism and gout had a depressing effect on the system, and were distinctly prejudicial. According to the germ theory of the origin of the disease, some antiseptic should be given, and guaiacol carbonate had been specially recommended in doses of five grains, three or four times a day. The diet should be most nourishing, and should consist of plenty of red meats, meat juice, milk, cream, and similar articles; and the food should be administered at frequent intervals. Hydrotherapy should be used with great care and discrimination. The sulphur waters were particularly beneficial. Local douching of the joints was not of much utility, but douching of the spine was of signal value. The immersion bath should be used cautiously, and should be of short duration and of moderate temperature, in order not to enervate the patient. Massage was also useful, but should not be too prolonged so as to cause fatigue. In many instances the deformity of the joints was due largely to contracture of the ligaments and tendons. It might be overcome by slow and careful stretching under ether, but the backward and forward movement often used in breaking up adhesions should not be employed in these cases.

DR. BEVERLEY ROBINSON said, regarding the bacterial origin of the disease, that it did not seem to

him there was as yet any very conclusive evidence in support of this view. Inasmuch as he had not met with cardiac complications and but seldom with visceral troubles, he was inclined to think that the affection was not rheumatic in character. Many of the joint lesions of arthritis deformans closely simulated certain lesions of the joints resulting from disease of the nervous system, notably Charcot's disease. The trouble in deciding upon the correctness of any one of these theories was that no single physician could have an extensive experience in the observation of cases of arthritis deformans. According to his experience the dietary of people so affected must be of a very simple kind and carefully selected. While he agreed with the reader of the paper that a systematic and prolonged use of the alkaline treatment for rheumatism in these cases was to be deprecated, he could not agree with him that the occasional, temporary, and judicious use of antirheumatic remedies might not be beneficial. In his opinion the intelligent and rational use of baths was productive of the greatest benefit. In a general way he favored the use of the waters from warm sulphur springs. In some cases persistent massage would be found most valuable, but it was not applicable to all cases. The *séance* should not be too vigorous, or repeated too often. He had found that these patients did not do well at the seashore, and that they did better if they spent their winters in warm climates. As to the diet, he favored the very cautious use of the dark meats, and a general abstinence from wines and beers. In the winter he relied chiefly on the continuous use of cod-liver oil, not having observed any marked results from iron and arsenic.

Dr. C. A. Herter said that, while the subject was one worthy of discussion, it was one which could be discussed only with great difficulty in the present state of our knowledge. Careful investigations were still lacking regarding many important points. Touching upon the etiology, he said that there were certain important similarities between the lesions of arthritis deformans and those associated with affections of the posterior nerve roots. The fact that there were muscular atrophies, that the skin was occasionally glossy, and that the nails were rigid in cases of arthritis deformans seemed to point to a nervous origin. We were yet very much in the dark regarding the influence of lesions in the posterior ganglia and posterior columns of the cord upon the changes in the bones and in the joints. Some of these cases had been shown, upon pretty good authority, to follow closely upon shock. The work that had been done by the propounder of the bacterial theory seemed to him to be rather crude and it had not as yet been sufficiently confirmed. Personally, he was disposed to regard the condition as one in which there were marked nutritive changes acting in connection with some peculiar constitutional condition. There were assuredly nutritive derangements in most cases of arthritis deformans. We were especially in need of early observations on such points. In his own observations he had found that the total acidity of the urine was a good deal larger than it commonly was, and he had also found evidence of excessive putrefactive changes in the intestine. These changes, however, were in no wise specific. As to the matter of diet, he believed that the carbohydrate element was the one which needs to be most restricted. A few years ago he had seen a girl of thirteen years, who had been allowed to live on all kinds of pastry and sweetmeats, with but little wholesome food. She took very little exercise. Gradually she developed a typical arthritis deformans. After a year's efforts to improve her nutrition, she was sent to California, where her diet was carefully restricted, and she was made to live properly and take long horseback rides, so as to cause free sweating. She had now been there two years, and the reports that he had received from a medical gentleman there were very encouraging. Dr. Herter said that he did not think there was any connection between lithæmia and arthritis deformans, for it was not uncommon for persons to remain markedly lithæmic for many years and yet develop none of the elements of arthritis deformans.

Prevent the Deformity.—Dr. W. R. Townsend said that the prevention of the deformity arising from arthritis deformans should be a part of the duty of the physician. A very little attention to position would accomplish very much. It was possible also to prevent much damage from pressure and friction. Within the last month he had applied in two cases of locomotor ataxia the simplest form of brace to the knee-joints, which were being worn away by friction.

Dr. Ransom, in closing, said that his treatment of this disorder had usually been directed to improving the nutritive state. It was in this way that he believed hydrotherapy acted favorably.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 21, 1898.

George Tucker Harrison, M.D., President.

Cystic Goitre—Operation.—Dr. Parker Syms presented a man, about sixty years of age, who had suffered from a slowly increasing tumor of the thyroid gland. This had become cystic at the time he had first come under the speaker's observation, about one year ago. As the growth pressed upon the trachea and caused great dyspnœa, he sought relief. Dr. Syms at once operated, removing a large cyst of the right side of the thyroid. He had found it possible to remove the cyst entirely by enucleation, the mantle of the thyroid being cut through and the cyst extirpated without rupturing the sac. The man made an uneventful recovery, and had since then been in perfect health. Both the specimen and the patient were submitted for inspection.

Dr. Thomas H. Manley asked if the goitre had developed as an acute or chronic growth; also as to the amount of hemorrhage, the manner of operating, and whether general or local anæsthesia had been employed.

Dr. Syms replied that the tumor was of the ordinary slow growth, the man having been aware of it for sixteen years, but it had finally broken down rapidly and become cystic. He had not felt that a local anæsthetic would be sufficient, in view of the great uncertainty regarding the extent of the operation that would be required. Ordinarily the incision should be a straight one in the median line, but this man had such a short thick neck that it became necessary to make an incision from the upper part of the median incision to the right for a distance of two or three inches. The remaining portion of the thyroid gland outside of the cyst was cut through, and the enlarged veins were tied off. It should be remembered that these veins required to be ligated with stout catgut, as the smaller sizes were apt to tear through. The man probably did not lose more than one ounce of blood in the whole operation. The wound was partly sutured, and partly packed, because of the great liability of infection taking place in the deep planes of the neck.

Dr. Robert Newman said that he was very much interested in this operation, because he had had the honor to assist, with Dr. Krackowitzer, in such an operation as far back as 1864. In this pioneer operation also the median incision had been used, and an attempt had been made to enucleate the growth, but

the vascularity was so great that each vessel, as it was reached, had to be doubly ligated and divided. There must have been at least fifty ligations in that operation. Only a few were present at the operation, and of these probably Dr. Lewis A. Sayre and himself alone survived. Eight days later, Dr. Newman said, he had performed a similar operation. Since then a number of these tumors had been treated by his friend, Dr. Charles R. Dickson, of Toronto. A photograph of one of these cases was shown. It had been first treated by electricity, and the tumor had been reduced in size a great deal in this way. The tumor proved to be malignant, and the patient died. In the year 1895 Dr. Dickson reported over one hundred cases of goitre treated by him. If the tumor was cystic he withdrew the contents, injected iodine, and applied a galvanic current. His plan was to apply the negative pole over the tumor and the positive electrode to the shoulder. Notwithstanding the success attained by this electrolytic treatment, Dr. Newman said he believed the operation of excision would maintain its position as an admirable procedure in certain cases. As the early operative cases he had referred to had not been reported, he mentioned them in order that they might be placed on record.

The remainder of the evening was devoted to an exhibition of lantern views of the region around Denver, *à propos* of the approaching meeting of the American Medical Association in that city.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 9, 1898.

T. Mitchell Prudden, M.D., President.

A Foreign Body Removed from the Abdominal Cavity.—Dr. H. J. Boldt presented a large gauze serviette and the portion of the bowel in which it had been lodged. He said that it was not at all uncommon for sponges, gauze compresses, and instruments to be left in the abdominal cavity through an error on the part of the nurse or by the oversight of the surgeon himself. He had been able to collect fifty-nine such cases, but that number could be quickly swelled tenfold if operators would publish accounts of their errors as well as of their successes. Only a few of these fifty-nine cases had been published. The two instances observed in his own practice were the following:

Case I.—This was a case of total extirpation of the uterus and adnexa for cancer of the uterus. A gauze strip had been lightly packed in the pelvis and the house surgeon directed to remove it per vaginam three days subsequently. This was done, but it was not noted that another had been substituted. The patient's convalescence was uninterrupted, but a few weeks after leaving the hospital she began to suffer from griping pain in the pelvis and abdomen, and from obstinate constipation. After about two months she passed a strip of gauze with a fecal evacuation, and then her pain and constipation entirely disappeared. Apparently the house surgeon had inserted the second piece of gauze beyond the edges of the vagina, and, the wound closing below the gauze, he thought it had been removed.

Case II.—The other case was one of abdominal hysterectomy for myofibroma. The operation was done in the early part of 1897, and convalescence was protracted on account of an abscess of the abdominal wall and phlebitis. The patient was discharged after the healing of the wound, but complained of constant pain midway between the umbilicus and the epigastrium. When she was seen in October, there was a swelling in this situation, which appeared to consist of adherent coils of intestine. On November 3, 1897, the abdomen was reopened and the diagnosis found to be correct, but the patient sank so rapidly during the disentanglement of the intestine that the operation could not be completed. An abdomino-intestinal fistula resulted, and, a fatal termination being inevitable unless relief could be afforded, the abdomen was again opened on January 10th. After an unusually difficult separation of the adhesions, during which the bowel was injured five times, a portion of distended bowel presented itself, and on examination of a rent in the bowel near this place a piece of discolored gauze was discovered. On withdrawal it was found to be the large gauze serviette that he had just exhibited to the society. The distended bowel immediately collapsed after the removal of the piece of gauze. The only explanation for its presence there was that the operating nurse had, in some way, made an erroneous report. The protracted convalescence had been due to the inflammatory changes caused by the foreign body gradually perforating the bowel, and this inflammation had caused the adhesions and tortuousness of the bowel, and had thus prevented the expulsion of the gauze in the natural way. The portion of gut injured during the operation was resected, and an anastomosis made with sutures. The woman died from shock two or three hours after the completion of the operation. The walls of the intestine exhibited great thickening as a result of the inflammatory changes set up by the prolonged irritation of the gauze. The speaker said that a study of these cases showed that the perforation of such a body into the intestine did not seem to be accompanied by any special symptoms. Unless such foreign bodies found their way into the small intestine the chances of their being expelled were good. If they did not perforate the bowel, they usually found their way to the surface and gave rise to local symptoms which led to investigation. In some instances the foreign body worked its way to the scar made by the primary operation, and there produced a fistula which, if enlarged, disclosed the nature of the trouble. As to the prevention of these accidents, Dr. Boldt said that surgeons differed. They all agreed that it was improper to use small pads or sponges as temporary packing, and that the sponges, pads, and clamps used should be counted before and after the operation. A good rule followed by some surgeons, to prevent leaving a clamp behind, was to ligate every vessel as soon as it had been seized and secured with the clamp. The method which he had himself recently adopted was as follows: If a small area in the pelvis was to be temporarily tamponed, a long strip of gauze was used, and either a long clamp was left attached to it or the end of the gauze was left protruding some distance from the abdominal cavity. For protecting the peritoneal cavity, sterilized towels were used in preference to gauze compresses. For smaller surfaces large gauze compresses were employed, and to these was attached a piece of silk or tape, and to the end of this a pair of forceps. No pad was permitted to be torn up for an emergency, and all pads discarded during the operation must be thrown into a special receptacle. All pads and forceps were controlled by double count before and after the operation. If a large number of small pads were required, they were never left in the cavity, even temporarily. By attaching tape and forceps to the gauze pads, the missing compress was readily found without unnecessary handling of the abdominal contents. The abdomen should never be finally closed until all pads and towels had been accounted for, and this counting should be done by the surgeon himself or by a reliable assistant.

Dr. Harlow Brooks said that he now had under treatment a patient in whom a foreign body had found

its way out through the original incision, forming a fistula. The patient, a young woman, had been subjected to ovariotomy in Philadelphia. Union had been delayed, and about one week after leaving hospital she had come to New York City. At that time there was a small discharge of pus from the lower part of the abdominal incision. The house surgeon introduced forceps and drew out a long piece of iodoform gauze. This was followed by the development of a hernia, but after a reparative operation she made a good recovery. The original operation had been done in the clinic of an eminent and notoriously careful surgeon.

Absence of the Vermiform Appendix.—Dr. Boldt then presented as an anatomical curiosity a cæcum that had been removed by him post mortem four or five weeks after a laparotomy. There was no trace of the appendix vermiformis—a condition which he understood to be quite rare.

Leukæmic Infiltration of Kidneys, Liver, and Heart.—Dr. J. S. Thacher presented sections, photographs, and drawings showing a leukæmic or lymphoid infiltration of the different viscera. The patient, a girl, three and one-half years old, was brought to the Presbyterian Hospital at 7:30 P.M., and died at 5 A.M. the following morning. The only history obtained was that she had been getting weak and anæmic, and had begun to have chills and sweatings about one month before. A few days prior to admission she had vomited blood and had also passed blood in the stools. On admission she was very cachectic, the spleen was much enlarged, and she had a bloody stool after an enema. The pulse was from 155 to 200; respirations, from 30 to 60; and the temperature, from 100° to 104.5° F. At the autopsy numerous ecchymoses were found beneath the endocardium and pleura, in the omentum, the mucous membrane of the stomach, the kidney, and the lungs. The heart muscle was fatty. The mesenteric glands were enlarged. Some of the blood from the heart was examined, and found to contain an abnormal abundance of white cells. Cultures from the lungs, liver, spleen, and kidneys showed pure growths of cocci which had a tendency to form short chains. Microscopical examination of sections of the heart, liver, kidney, and stomach showed areas containing small cells, the nuclei of which were usually small, rounded, and oval. The contents were granular and stained rather deeply with hæmatoxylin. The cell bodies were not appreciable, nor could any fibres be detected between the cells except where the latter had invaded fibrous tisue. These areas occupied about one-third of the total liver sections and one-half the area of the kidney sections examined. The proper tissues of the organs seemed to be scarcely affected by the presence of these areas. From these facts he had concluded that it was a leukæmic or adenoid infiltration rather than an inflammation.

Dr. C. A. Herter said that he had had an opportunity to examine these specimens previously, and he had shown them to Dr. W. H. Welch, who had been much interested in them. The latter gentleman had expressed the opinion that the lesion was a leukæmic infiltration rather than an inflammation.

The President also thought it a leukæmic infiltration. The case, he said, was particularly interesting because of its extent. In regard to nomenclature it was a question whether such infiltrations should be called "adenoid." He thought the whole matter would be clearer if we abolished the term "glands" for lymph nodes, and he suggested the term "lymphoid" or "indifferent cell" infiltration as applicable to the condition under discussion.

Dissecting Aneurism.—Dr. George P. Biggs presented a specimen showing a dissecting aneurism of the aorta. It was obtained at autopsy on a colored man, aged thirty-five years, a waiter by occupation, who was admitted to the New York Hospital on January 21, 1897, with the following history: Never had rheumatism; alcoholic habit marked; no evidence of syphilis except a few suspicious scars on the legs. He had had cough for some time, but otherwise he was well until one month before admission to the hospital, when the cough became more troublesome and severe attacks of dyspnœa developed. Since that time he had steadily lost flesh and strength; the legs had become swollen and the dyspnœa more constant. Physical examination: Harsh breathing and a few moist râles over both lungs; heart moderately hypertrophied, the apex being felt in the sixth intercostal space five and one-half inches to the left of the median line; systolic and diastolic aortic murmurs quite pronounced. The case was under observation for three months and during that time the urine contained from five to twenty per cent. (by bulk) of albumin; the pulse was from 80 to 120, and the temperature from 99° to 100° F., except one month before death, when for three days it rose to 101° and 104° F., and marked pulmonary signs developed on the right side. Death resulted from heart failure and pulmonary œdema. The autopsy showed general anasarca and chronic venous congestion. A large thrombus occluded the branch of the pulmonary artery going to the right lower lobe of the lung and practically converted the whole lobe into a red infarction. The remainder of the lungs was congested and œdematous. The heart was considerably enlarged, the cavities being dilated and their walls thickened. The valves were normal except the aortic, the cusps of which were considerably thickened and retracted. The muscular substance appeared normal. There was considerable dilatation of the pulmonary artery, due evidently to induration about it and compression of it as it passed under the aortic arch. The coronary arteries and aorta were moderately atheromatous. At the junction of the transverse and descending portions of the aortic arch, and looking to the left, there was found an oval opening measuring three and one-half centimetres antero-posteriorly and one centimetre vertically. The opening had a perfectly smooth, rounded border, and led into an old dissecting aneurism, the wall of which was formed exclusively by the adventitia and external layers of the media of the aorta. In its upper portion the aneurism was to the left of the aorta, but in the greater part of its course it lay in front of it and caused almost complete flattening of the aorta against the spinal column. The aneurism measured twenty-three centimetres in length and four centimetres in diameter, and it terminated by communicating again with the aorta a little below the cœliac axis, through an oval opening measuring two centimetres by one centimetre. The lining of the sac had practically the same appearance as that of a dilated, atheromatous aorta. Most of the intercostal arteries arose from the aorta, but the eighth, ninth, and tenth left arteries came directly from the aneurism. The cœliac axis also arose from the aneurism, but there was an opening of the same size exactly opposite it, in the anterior wall of the aorta, which undoubtedly indicated the original connection of the vessel with the aorta. The force of the blood current would easily explain the obliteration of the portions of intercostal arteries and the cœliac axis which at first traversed the aneurism. Dr. Biggs said that the specimen was very similar to one presented to the society about two years ago by Dr. Herbert Williams, of Buffalo, who at the time considered it a double aorta but later concluded it was a dissecting aneurism.

Dr. H. N. Heineman said that it had been fairly well established that dissecting aneurisms were the result of traumatism. The traumatism was usually at

the base of the aorta, and assumed the form of a transverse break in the aorta, which was in direct opposition to what took place when there was fatty degeneration of the intima and media, for in the latter case the rupture was longitudinal. Such a dissecting aneurism might heal, or might be carried by the person for many years without special discomfort. Meanwhile the aneurism dissected its way down to the cœliac axis, or to the renal arteries, and then found its way back to the aorta. This was the reason why the person did not die immediately from it. There was a very remarkable specimen in the museum of Giessen University, which had been taken from a man who thirteen years before, after having been injured in a scrimmage, had developed what was then supposed to be heart disease. He recovered from this, and thirteen years later died under the observation of one of the professors who had seen him in the first illness. The post-mortem examination showed a dissecting aneurism of the aorta.

A Valvular Lesion with Disappearance of Vegetations.— Dr. W. B. Noyes presented the heart of a child of thirteen years who, for seven months before admission to the hospital, had suffered from cough and shortness of breath and pain in the cardiac region. The heart action was rapid, the respirations were accelerated, and the expectoration was at times bloody, but no murmur was heard. The child died suddenly a week after admission, with no special premonitory symptoms. At the autopsy the mitral valve was found to be reduced to the size of a lead pencil, but there were no vegetations on it. The right heart was very much dilated. The specimen was presented as an instance of a valvular affection which had originated from a rheumatic endocarditis one year before, the fresh vegetations having disappeared. There was, of course, a possibility of the lesion being congenital. During life the affection of the heart had been considered to be functional.

Extreme Mitral Stenosis and Dilatation of Both Auricles, with Large Organizing Thrombus of Left Auricle.—Dr. Eugene Hodenpyl presented this specimen together with microscopical sections. It had been removed from a man, seventy-four years of age, who for many years had suffered from chronic diffuse nephritis, repeated attacks of asthma, and bronchitis. He died during an asthmatic attack. At autopsy the right auricle was found enormously distended with recent blood clot, which extended into the larger branches of the pulmonary arteries. The left auricle was distended and firm. Its cavity was filled with an old decolorized clot firmly adherent to the wall of the auricle. This showed evidence of organization about its periphery. There was extreme stenosis of the mitral orifice.

(To be Continued.)

Pyæmia.—There are very few terms in surgery so confusing as the name pyæmia. It has been used by different authors to include all the varieties of traumatic fevers, while it is recognized that some of the symptoms are seen only in rare cases. It seems to me we can safely restrict the term to a distinct disease characterized by a state of depression common to all typhoidal conditions but distinguished by the formation of pus cavities in different and widely separated parts of the body. No tissue may be exempt. Abscesses have been found in the lungs, liver, kidney, joints, muscles, bones, brain, lymphatic glands; coagulability of the blood is diminished, and there is leucocytosis with purulent effusions into the serous cavities. The disease is contagious, being communicable by instruments or sponges in the hands of the surgeon or other attendant, and passes along the vascular or lymphatic channels.—Edmund W. Holmes.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A FURTHER DISCUSSION ON CANCER OF THE BREAST—INTERMENSTRUAL PAINS—PERILS IN PRACTICE—DIPHTHERIAL INFECTION—ANTISTREPTOCOCCAL SERUM—MIDDLESBOROUGH EPIDEMIC—DIPHTHERIA IN LONDON—GLYCERINATED LYMPH—SIR R. QUAIN—UNREGISTERED BUT PRACTISING—UNQUALIFIED ASSISTANTS—DR. R. RUSSELL.

London, March 11, 1898.

The subject of extensive operations for mammary cancer has received further illustration in our societies. Mr. Clinton Dent related at the Medico-Chirurgical Society meeting on Tuesday a case in which he had removed an entire upper extremity for recurrent carcinoma after amputation of the breast. The woman, aged fifty-three years, had the left breast removed in December, 1894, and the axillary glands were also freely removed. In 1896, a recurrent nodule near the cicatrix was removed. In October, 1897, recurrent ulcerating growth high up in the axilla, great swelling in the arm, and intense pain were met by removal of the arm, scapula, and the outer two-thirds of the clavicle. The subclavian artery, scapular branches, and the vein were tied after removal of part of the scapula; there was no shock. Only two or three ounces of blood were lost. The patient left for a convalescent hospital on the twenty-sixth day. The growth had encircled the axillary artery and vein and the main nerve trunks. The coracoid process was replaced by the growth, which was columnar celled (duct cancer), in which recurrence is unusual. Mr. Dent laid down the indications for and against such an operation, and said he had seen the patient within the last few days, and found there were signs of deposit in the liver which were not present when he operated. There was also some growth on the thorax, but the operation had entirely relieved her of the distressing pain, and he would do it again in an equally urgent case.

Mr. Willett and Mr. Boyd both supported the propriety of the operation as giving great relief. One of them had recommended it to two patients, but neither of them had been willing to undergo it.

At the Obstetrical Society meeting the subject of intermenstrual pain was discussed. Dr. Addinsell introduced the subject, and related four cases of his own and compared them with those recorded by others. In most cases, besides pain of so marked a character that it had been sometimes improperly termed intermenstrual dysmenorrhœa, the most marked symptom was a clear watery discharge. Dr. Addinsell attributed this to a tubal lesion leading to hydrosalpinx, and suggested as the cause a secondary intermediate discharge of nerve energy in certain individuals—an explanation which explains little.

Dr. Herman said there was certainly present or past disease of the appendages in many cases. He thought the pain was due to painful ovulation, not coincident with menstruation, and was sceptical as to dilated tubes being the source of the discharge. If a dilated tube be lifted up during an operation the fluid does not escape. He would call it intermediate monthly pain, a name which had the merit of being simple and sufficiently distinct.

Mr. Bland Sutton admitted that if the blood pressure within the tube reached a certain pitch blood might escape into the uterus, but this must be exceedingly rare, and we had no clear evidence of such an occurrence. Dr. A. Routh suggested that in some persons an intermenstrual cycle was added to the menstrual one.

Dr. Boxall thought no single pelvic lesion would explain the cases. He had attended a case in which there had never been any sign of tubal disease. The pain returned after an abortion had occurred through a cycling imprudence. The patient became pregnant later on, though there had been retroversion.

Dr. Heywood Smith held to the notion of intermittent Fallopian hydrorrhœa.

Dr. A. Giles said that admitting menstrual congestion could occlude the uterine ostia of the tubes, accumulation might occur and lead to pain. On the cessation of menstruation the swelling would go down and the fluid in the tubes pass into the uterus.

Dr. E. Maclean thought some cases might be regarded as an attempt at double menstruation.

The president (Dr. Cullingworth) observed that in only three of the thirteen cases cited was there a distinct tubal lesion. He had known bath water to be pent up in the vagina and subsequently discharged, and in another case urine, so that caution was necessary in admitting that the escape of fluid indicated a tubal source, which was extremely unlikely.

Dr. Addinsell in his reply said that in his own cases he had found a swelling which disappeared after the discharge of the fluid.

Unpleasant reminders of the perils of practice have lately occurred. A boy was admitted to one of our hospitals for a chronic disease requiring operation. In a few days he was seized with dyspnœa, which became so urgent and seemed of so obstructive a nature that one of the surgeons called to see him hastily performed tracheotomy. A little blood entered the trachea with the tube. The aspirating-apparatus had not been brought with the other instruments and the surgeon sucked the tube. Two days later he was seized with sore throat, and as the boy in the mean time had clearly developed diphtheria, bacilli having been found, the surgeon had antitoxin injected as a precaution and a bacteriological examination of his own case made. The result was that bacilli were found; he was isolated and treated actively with antitoxin. He passed through a mild illness, but bacilli persisted for four or five weeks, and he had to take a holiday before being restored to his family.

A more serious case is that of another hospital surgeon, who wounded his finger when examining a tuberculous bone and had antistreptococcal serum injected. Reaction speedily ensued and he went through all the horrors of septicæmia. No doubt the serum was impure, you will say; but that illustrates a danger too apt to be present. This serum is a two-edged weapon, and from all the evidence that has been accumulated seems to be useless against any organism except the streptococcus. How injurious it may be, was shown in a case lately reported to the Liverpool Medical Society. It was given in puerperal fever and followed by thrombosis and nephritis. On examination the dried serum was found to contain streptococci, evidently due to defective filtration. The utmost care then is demanded in such cases, and indeed it would seem as if every serum might well be re-examined immediately before use.

"Only eleven cases of small-pox were notified yesterday." That is the report from Middlesborough, and, though it seems hopeful to some of the people there, it shows that the epidemic is by no means over. Other days during the week have had as many as seventeen, nineteen, twelve, or thirteen fresh cases.

The notified cases of diphtheria in London for the four weeks of February were 939, the weekly average 235. In the January four weeks the average was 225; total, 901.

Glycerinated calf lymph is to be brought into general use as rapidly as possible.

Sir Richard Quain has been in feeble health for some time. To-day the venerable baronet's condition is reported to be critical. He retains his interest in the Medical Council and other matters. At a meeting of the executive committee of the council on the 21st ult., a letter from him was read, dealing with the forthcoming pharmacopœia.

A summons against a person who had continued practice after the Medical Council had erased his name from the register was this week refused by a magistrate, who said he could find nothing in the medical act to compel a man to be registered. Of course the council must take other proceedings.

The cause of unqualified assistants has been taken up by *Truth*, with the mixture of invective and ignorance which so often characterizes that journal.

Dr. R. Russell has been appointed assistant physician to University College Hospital.

THE PERILS OF ANÆSTHETIC MIXTURES.

To the Editor of the Medical Record.

Sir: The Schleich method of anæsthesia seems to have become very fashionable since the publication of Dr. Willy Meyer's article a few weeks ago, and the general impression seems to be that it is far less dangerous than anæsthesia by ether or chloroform alone.

I must say that my faith in the safety of anæsthetic mixtures has been low since I saw a young and apparently healthy man die on the table in Billroth's clinic eighteen years ago. I shall never forget the scene.

The patient had been brought in for the reduction of a luxation of the hip-joint, and the anæsthetic, a special mixture of Billroth's own, consisting of alcohol, ether, and chloroform, was being administered in the careful manner always employed in this amphitheatre.

Billroth had just reduced the luxation and had turned to talk to the class, when the assistant called his attention to the condition of the patient, who had stopped breathing. The professor turned hurriedly to the patient, and by means of artificial respiration everything seemed restored to a normal state. Turning again to the class, Billroth said, "Thank God he is all right." Then he went on to state how safe he considered this mixture and how he had never had an accident under it. Again his attention was called to the patient, and then for the only time during my attendance on his clinics the great surgeon showed signs of extreme excitement. Artificial respiration and every other restorative measure were tried. Billroth's hand shook like a leaf as he hurriedly performed tracheotomy, but all to no effect. The man was dead.

The next day after a post-mortem examination Billroth stated that no lesion of any kind was apparent, and that he could account for the man's death only on the score of idiosyncrasy. Last week I had an experience with the use of Schleich's mixture and for the time I thought I had a corpse instead of a patient on my hands.

I had arranged to circumcise a young man, about twenty-eight years of age, at his father's house, and, as my experience with the Schleich mixture had been favorable up to that time, I concluded to use it. My assistant is an expert in giving anæsthetics, so that I know that everything was done correctly.

During the first period the patient was very hilarious, then he breathed badly, and my assistant said afterward that his pulse was variable; but this might have occurred under any anæsthetic, from nausea, or as it frequently does in half-narcotized patients, so nothing was thought of it.

I had just snipped off the end of the foreskin when the anæsthetist asked me for a pair of tongue forceps.

I thought the patient dead; his pupils were dilated, breathing had stopped, and the pulse could not be felt. His jaw dropped and the face was cyanosed. I confess that I was thoroughly frightened, but with stimulation, artificial respiration, and moving the tongue outward and inward, the functions of life slowly returned.

The operation was finished without any further administration of an anæsthetic, and I have decided that in the future I shall use straight goods instead of mixtures. The trouble is, one never knows exactly what he is giving. The differing densities of the various components cause them to separate, and one can never be sure whether he is giving a larger proportion of one or another. I have had what seemed dangerous conditions present themselves many times before, but nothing like this.

SIDNEY F. WILCOX, M.D.

51 WEST FIFTY-SECOND STREET.

ANTIPYRIN AS A LOCAL ANÆSTHETIC.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I desire to call attention in this preliminary note to what promises to be a new departure in genito-urinary surgery. I have used, as a substitute for cocaine in a number of cases of urethrotomy, a ten-per-cent. solution of antipyrin in a one-per-cent. solution of carbolic acid. As far as my observations have gone, the solution appears to be quite as efficacious as cocaine. In meatotomies, when, as is well known, the skin incision is usually painful, I have found even less complaint than when cocaine is used.

The advantages of the agent as compared with cocaine are 1, absolute safety; 2, freedom from constitutional effects; 3, distinct lessening of hemorrhage, both before and after operation; 4, less disturbance of nutrition of the wounded tissues.

I have thus far used only a ten-per-cent. solution of antipyrin. I have not experimented as yet with a simple aqueous solution. The solution should be fresh, and should be allowed to remain in the urethra for ten minutes, as a rule. I have, however, begun cutting within five minutes after injecting it. I would suggest the antipyrin solution for nose and throat work. It will at least make a safe foundation for further anæsthesia with cocaine. Absorption of the cocaine and hemorrhage will both be inhibited, thus adding greatly to the safety of operations. Unlike that of cocaine, the styptic effect of antipyrin is not followed by vascular relaxation and often almost uncontrollable hemorrhage.

G. FRANK LYDSTON, M.D.

CHICAGO, ILL., March 17, 1898.

DOES FORMALDEHYDE DISINFECT?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: During the past year much interest has been manifested by sanitarians in the promise of a new disinfectant—formaldehyde.

This substance has been lauded by several writers in the medical press as the disinfectant *par excellence*, a substance which, in its gaseous state, none of the lower forms of life could successfully resist. Experiments undertaken by some investigators known to the medical and scientific world have been cited by the manufacturers of formaldehyde and by the makers of the different forms of apparatus for the generation of formaldehyde gas. Most of these experiments have been conducted in laboratories where it would seem that every necessary convenience would be provided for determining the true efficiency of this new agent. Laboratory experiments are not, however, always borne out by work in practice. For instance, many of the laboratory experiments undertaken with formaldehyde are found to have been made upon dry cultures of diphtheria, typhoid, and anthrax bacilli exposed to an atmosphere of formaldehyde gas for varying lengths of time. Experiments may have been made upon plate or tube cultures, but favorable reports of such experiments have not come to my notice. Laboratory experiments conducted with dry cultures do not seem to be all that is necessary in practice. In practical disinfection where diphtheria or tuberculosis occurs (the two chief diseases for which a gaseous disinfectant is wanted), we do not always find the bacilli dried and hung out ready for a disinfectant. If cleaning is done in an infected house into which the practical work of disinfection is carried, and any nests of infection remain, there will necessarily be closely associated with these foci of infection a certain amount of moisture. Under such conditions formaldehyde disinfection has not been successful in our hands. On the other hand, if cleaning is not used before formaldehyde disinfection, there would necessarily be a larger number of foci of infection to be destroyed. The action of formaldehyde in vapor must necessarily be very great, and its penetrating power far greater than has been proven by favorable experiments. Recent teaching based upon bacteriological studies has been that thorough cleaning with good soap and clean water intelligently applied is the best means for ridding premises of infectious material, and that after thorough cleaning disinfection should be used as a supplementary measure. From some of the experiments with formaldehyde, it would appear that, as formaldehyde operates best on dry media, cleaning should be dispensed with because of the necessary moisture.

A series of five experiments has been conducted in the laboratory of the Rochester health department—four of them to determine the efficiency of formaldehyde in practice, the fifth to determine the efficiency of sulphur as compared with formaldehyde.

EXPERIMENT 1.—Apparatus used according to directions in a room containing less than fourteen hundred cubic feet and having a considerable amount of laboratory furniture. Amount of formaldehyde vaporized, six ounces. Material exposed, three tubes of mixed cultures of diphtheria bacilli upon nutrient blood serum in open Petri dishes, a quantity of sputum containing tubercle bacilli in a shallow wide-mouthed bottle, and four tubes of mixed cultures of diphtheria bacilli. Time of exposure, five hours. Result: tubes inoculated from the cultures all showed good growths at the end of twelve hours.

EXPERIMENT 2.—Cultures of diphtheria and sputum containing tubercle bacilli were exposed in the same way and under the same conditions for six hours. Amount of formaldehyde vaporized, eight ounces. Inoculations from the cultures exposed upon appropriate media all showed that the diphtheria and tubercle bacilli in the cultures and sputum had not been destroyed, nor had their power for growth been perceptibly interfered with.

EXPERIMENT 3.—Cultures of diphtheria bacilli and sputum containing tubercle bacilli exposed as in experiment 1. Result: similar to those of experiments 1 and 2. In this experiment eighteen ounces of formaldehyde was used.

EXPERIMENT 4.—As objection was made that the room in which experiment 3 was conducted was not tight enough, although the door casings and casings about the transoms were fitted with rubber weather strips, additional means were taken to prevent the escape of gas by caulking with paper the spaces about the door casings and transoms. Amount of formaldehyde vaporized, thirty ounces. Time of conducting the experiment while the lamp of the apparatus was

still burning, forty-five minutes. Material exposed similar to that in experiment 1. Result: similar to that in experiment 1.

Experiment 5.—Four pounds of sulphur burned in the same room in the presence of steam generated from two quarts of water in a basin eight inches wide placed over a two-flamed Bunsen burner. The cultures made after six hours' exposure showed no growth. Furthermore, several unused tubes of Loeffler diphtheria serum inadvertently left in the room were afterward found to have been rendered useless by the sulphur fumes. No growth could be obtained in these tubes, even though carefully inoculated with an abundance of mucus from the throats of patients having diphtheria.

The results of these experiments lead me to believe that the value of formaldehyde as a disinfectant, with a sufficient penetrating power thoroughly to disinfect in practice, has not yet been proven.

G. W. Goler, M.D.,
Health Officer, Rochester, N. Y.

March 12, 1898.

A FINAL WORD TO DR. W. MEYER WITH REFERENCE TO THE USE OF THE CYSTOSCOPE IN PROSTATIC HYPERTROPHY.

To the Editor of the Medical Record

Sir: Dr. Meyer, in his reply to me in the March 26th number of the Medical Record, defines what he meant by the term "configuration" in the sentence, "We can very well diagnose the configuration of the prostate with the help of the cystoscope," in the following words: "I meant, of course, that we can diagnose with the cystoscope whether the prostate is hypertrophied or not; if so, whether this hypertrophy is a pronounced or a slight one; whether there is a third lobe or not." If that is all he means by configuration, then I am sure that I can see as much as he can. I judged from statements made by Dr. Meyer in the article wherein he misquoted me and also elsewhere in his answer to me, that he laid claim to being able to see more than that. If that is all that can be seen, then it would be impossible for one to make from the cystoscopic picture a drawing or a clay model which would accurately represent the real state of affairs—which would be my idea of "configuration."

I have no desire to decry the value of the cystoscope. I depend much upon it. There are, however, limits to its usefulness, and the instrument is not helped with the profession by the extravagant claims which are sometimes made in its behalf.

Eugene Fuller, M.D.

New York, March 26, 1898.

Alcohol as a Hypnotic.—Mr. Jonathan Hutchinson says: "I was urging strongly on a man who well knew his failing that he should reduce his quantity of whiskey. In giving a reluctant assent, he remarked: 'But, you see, it gives me sound sleep. If I do not take my normal allowance at bedtime, I dream dreadfully all night; but if I have had it, why, I sleep like a child and never dream at all.' 'But,' I suggested, 'do you not wake with a dry mouth and a headache?' 'No,' he said: 'I wake as bright as possible and enjoy my breakfast.' The latter point was confirmed by the fact that he had a perfectly clean and soft tongue. He had, as he well recognized, been on the verge of delirium tremens more than once, and was anxious to amend his mode of life. What made it especially difficult for him was that alcohol always seemed at the time to suit well and never gave him at the time any immediate discomfort. There are many who are, I believe, in the same position as my patient, and those may be thankful in whom indiscretions and excesses are followed by prompt and well-recognized penalties."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending March 26, 1898:

	Cases.	Deaths.
Tuberculosis	176	129
Typhoid fever	8	1
Scarlet fever	189	15
Measles	400	16
Diphtheria	147	19
Laryngeal diphtheria (croup)	10	3
Chicken-pox	31	0
Cerebro-spinal meningitis	5	4
Pertussis	2	0
Erysipelas	2	0
Parotiditis	1	0

The First Thermometers.—The *Revue des deux Mondes* has an extremely interesting article on the above subject, which has been translated and published in *Appleton's Popular Science Monthly* for March, some of which is quoted below: "According to the Abbé Nollet, the first thermometer was invented by a peasant named Drebbel, of North Holland. Drebbel's thermometer was composed of a vertical glass tube ending at the top in a bulb, while the lower end was plunged into a vessel filled with water or some colored fluid. When the bulb was warmed, a part of the air contained within it was driven back into the water and escaped without. When the air became as cool again as the temperature around it, the external pressure caused the liquid to rise in the tube, the limit of its ascent being determined by the degree to which the air in the bulb had been heated and the tension it had acquired. The members of the Accademia del Cimento soon substituted for this hardly practical apparatus the more convenient instrument which we still use. The Venetian physiologist Santorio Santori made it a sensitive and precise indicator of the progress of fever. Réaumur observed in 1730 that a thermometer placed in freezing water went down to a certain degree and remained fixed there as long as the water was not wholly solidified, and, therefore, came to the conclusion that the temperature of water in process of congelation was always the same and fixed. Subsequent researches showed that the melting-point of water was the fixed one. Alcohol thermometers were used until Misschenbroeck introduced the use of mercury. It was some time before the two fixed temperatures at which the thermometric scale should be marked were determined upon. Dulencé in 1688 took a mixture of water and ice for the zero and the melting-point of butter as the upper point. Renaldini in 1694 recommended a mixture of water and ice, and the boiling point of water, but his process was not applicable to the alcohol thermometers, for the vapor of alcohol has a tension at the boiling-point of water which would burst the reservoirs of the instruments. About 1714 Daniel Gabriel Fahrenheit furnished chemists with alcohol thermometers, which he replaced in 1720 with mercury thermometers, and took for his zero the temperature of a mixture of ice and muriate of ammonium, and for his highest degree the temperature of the human body. In 1742 Andrew Celsius proposed to restore the method of Renaldini and divide into a hundred degrees the interval which the mercury in the thermometer would traverse between the temperature of melting ice and that of boiling water. He marked the lower temperature 100 and the higher 0. Linnæus, reversing this order, gave the mercury thermometer (Centigrade) the form under which it is now known

The Myophone.—A French scientist has proved, with an apparatus called the myophone, that the nerves may live many hours after the death of the body. The sound in the instrument shows that a nerve may act on a muscle in a state of electric excitability, without producing more than molecular vibration.

The Story of a Barber Surgeon.—According to the London *Daily Telegraph*, an inhabitant of a little village near Mainz fell down and seriously injured his arm, which became swollen and very painful. The village barber surgeon was appealed to, and ordered applications of Goulard water—in German, Bleiwasser. The patient's wife, however, being very anxious, on arriving at the village shop made a mistake and asked for Wasserblei, or black lead. On arriving home she mixed this with water and rubbed it well over the injured arm, finally polishing the limb with flannel. The treatment had an excellent effect—the pain disappeared and the swelling went down. Next morning the barber called to see how the patient was getting on, and was met by the delighted wife, who congratulated him on the efficacy of his treatment. Upon seeing the arm, however, which was quite black, he was horrified. "What!" he said, "no pain! Of course he doesn't feel any pain. The arm is quite dead; gangrene has set in, and if the arm is not taken off at once he will die." A surgeon was sent for, who of course discovered the real state of the case. What happened to the barber is unfortunately not stated, but we fear that most unqualified practitioners do not see such favorable results from their prescriptions as did their German brother.

Anæsthetics Administered in the London Hospital from January 1 to December 31, 1897.—Ether in 2,910 cases, nitrous oxide in 1,362 cases, chloroform in 677 cases, A. C. E. in 510 cases. Ether followed by chloroform in 293 cases, nitrous oxide and oxygen in 240 cases. Nitrous oxide followed by ether in 220 cases, ether followed by A. C. E. in 82 cases. Nitrous oxide, ether, and chloroform in succession in 68 cases, A. C. E. followed by ether in 35 cases, other successions in 93 cases. Not stated, 167. Total, 6,657.

Effects of Alcoholic Excess on Occupational Mortality.—The experience of the period 1890–92 agrees with that of earlier periods in showing that publicans (saloon keepers) as a class succumb to the effects of intemperance much more rapidly than men engaged in any other occupation. Of the two divisions of the publican class, innkeepers suffer from alcoholism and diseases of the liver more severely than their servants do; the former die from these diseases more than seven times faster and the latter four times faster than other occupied males. The mortality of publicans varies according to the locality in which they trade; they die most rapidly in the industrial districts and least rapidly in London. Next to publicans come butchers, with a mortality figure from intemperance which is two and a fourth times as high as that of occupied males generally. Among the remaining occupations in the list chimney sweepers and dock laborers suffer most severely from alcoholic excess, while coachmen and cabmen suffer least severely, the mortality of the last two from alcoholism and liver diseases exceeding that of other occupied males by about one-half.—*Lancet.*

British Women Doctors.—There are two hundred and forty women on the medical register of Great Britain. Over fifty are established in London, quite as many are absorbed by missionary work, etc., in India and the East generally; the provinces claim about sixty; a few have gone to the colonies or have settled in continental resorts. The remainder are either taken up with hospital work or are not practising. A considerable number of medical institutions for women and children are officered wholly or partly by registered medical women. In London there are nearly a dozen such, including the Royal Free Hospital, Gray's Inn Road, and the New Hospital for Women, Euston Road. As more than half the population of Great Britain is female, the proportion of women doctors is still extraordinarily small, for there are no fewer than eighteen thousand members of the British Medical Association alone. But if women have not rushed to doctor their own sex in the numbers anticipated, the movement is still, I am glad to acknowledge, an eminently respectable one. On the part of the Royal College of Physicians and the Royal College of Surgeons, opposition to it has almost died out, and the road to a medical qualification lies open to women through the University of London, the Scotch and Irish universities, the University of Durham, the conjoint colleges of Scotland and of Ireland, and the Apothecaries' Society of London. Of schools at which they can study medicine, there is in the United Kingdom no stint. The London School has at present, I am told, one hundred and sixty-three students; there are two schools in Edinburgh, two in Glasgow; likewise schools at Newcastle, Aberdeen, Dublin, Cork, and Belfast. Naturally the medical career remains to a certain extent exclusive, by reason of its cost, though not more so to women than to men. The course of study takes at least five years, and its average length is more like seven, during which time, of course, the student has to be supported. What the chances are of a medical woman earning an adequate income it is difficult to say, but some of them certainly do well, as one may judge by the establishments they keep up. They are to be found in most of the expensive quarters of London. One more fact I must append, as it bears upon the question of the relations of women to doctors of their own sex. "The New Hospital charges its patients a small fee, two pence (four cents), each visit, and sixpence (twelve cents) the first time. These fees amounted in 1895 to £1,231 7*s* 6*d* (about $6,000). The significance of these figures will be seen when it is added that within a few minutes' walk of the New Hospital on either side are the Royal Free and University College hospitals, at both of which women could be attended for nothing by men. In one or two respects the woman doctor remains unquestionably handicapped. Unlike the male practitioner, she must draw her patients chiefly, if not entirely, from among women; and if she ventured to purchase a partnership along with a male practitioner, people would talk—would they not?—despite her diplomas.—*London Referee.*

Jewels Affected by Ill Health.—Professor von Schroen, of the Naples University, declares that diamonds are alive. Be this as it may, there would appear to be many reasons for believing that some precious stones are affected by the health of the wearer. A contribution to an English weekly journal says: "Pearls and opals are both said to grow dull through the ill health of her by whom they are worn, and the turquoise is said to become pale from the same cause: while I have heard, and on excellent authority, though it is a fact I can hardly credit, of a ruby ring which on the hand of an invalid went paler and paler until on the patient's death the stones lost their color entirely. Pearls are extraordinarily sensitive to the condition of the skin on which they rest. An example of this fact is shown by an episode of which an acquaintance of my own was the heroine. She greatly desired to possess a pearl necklace, and her husband bought her a very

beautiful one. A month or two afterward, however, the pearls began to lose their lustre, and, much annoyed, he took the necklace back to the jeweller who sold it to him. The salesman admitted the deterioration. 'You are quite right,' he said; 'but the truth is that your wife cannot wear pearls next her skin. Let her maid wear the necklace for a few weeks, and the pearls will regain their brilliancy.' The turquoise, again, will change color. I know of one which, after having been worn for years, turned a vivid green when its wearer was passing through the Red Sea; possibly it was affected by the temperature of her skin. It is probable that the turquoise has a form of life, as pearls undoubtedly do. A pearl dies as actually as a flower, though its life is a great deal longer, and all its color and brilliancy disappear. Its average life it is impossible to estimate, as some pearls are known to be hundreds of years old; but it is probable that the life of others is far shorter."

Anæsthesia by the Schleich Method.—Drs. Stillman and Greeley, of the New York Infirmary for Women and Children, report forty-four cases anæsthetized by the Schleich method during January and February. These cases include five laparotomies and a large proportion of double and triple vaginal operations. The average length of operation was fifty-two minutes. The average total quantity of anæsthetic employed was three and one-third ounces, of which amount seven-eighths of an ounce was required to induce anæsthesia in an average period of ten and one-half minutes. The patients recovered consciousness in fourteen minutes. During the following twenty-four hours eighteen were considerably nauseated, three of them more so than after ether administered at previous operations. In one case there was mild excitement during recovery, for half an hour only. Three cases required stimulation; in one of these ether was substituted because of a persistently weak pulse. Three cases, not the above, had valvular lesions of the heart. In general the pulse and color were good; in the earlier cases less so, the cause, in the opinion of the anæsthetizer, lying in the fact that the vapor was too concentrated. Mixture No. 1 was used in twenty-four cases, No. 2 in sixteen, No. 3 in four. The muscular reflexes were difficult to control with No. 1, and No. 2 or No. 3 would be used in a larger proportion of cases again. The inhaler employed was the Esmarch covered with a single thickness each of gauze, flannel, and oiled muslin. With a few exceptions the patients received the customary hypodermic of one-eighth of a grain of morphine and one-one-hundred-and-fiftieth of a grain of atropine half an hour before operation.

Heat in Australia.—A correspondent from Australia writes to the *London Times*, in reference to the late heat wave in that part of the globe, as follows: "When we reached Melbourne we found the thermometer at 108° F., with a good stiff breeze like the blast from a furnace. The whole country was enveloped in bush fires, and the sun looked as it does in London through a November fog. The haze was so great that after proceeding for about two hours on our course through Hobson's Bay we had to drop anchor, as the pilot could not discern the channel. We were thus unable to move till midnight. For some hundreds of miles up the coast the bush fires continued to rage. The sight was a curious one, for the ship was invaded by parrots, cockatoos, and other land birds, which were forced out to sea by the flames and intense heat. Besides the birds, burnt leaves, charred wood, and small stones were picked up on deck, although we were several miles from land. The sky was very lurid at the time."

The Bones of Sir Thomas Browne.—The Rev. Pelham Burn is the rector of St. Peter's Mancroft Church, Norwich, England. Certain changes of the convenience of the choir were thought necessary in the church, notably the lowering of the floor. But it happens that in this choir lie the mortal remains of Sir Thomas Browne, one of the most famous of English physicians and author of the well-known "Religio Medici." When Mr. Burn was asked if he did not feel some respect for the last resting-place of Sir Thomas Browne, his answer was facetious: "Yes, he is buried there; we shall probably see him again."

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

HOW TO BECOME A TRAINED NURSE. By Jane Hodson. 8vo, 260 pages. Illustrated. William Abbatt, New York.

A NEW DIAGNOSTIC SIGN OF MEASLES.

BY HENRY KOPLIK, M.D.,

ATTENDING PHYSICIAN TO THE GOOD SAMARITAN DISPENSARY, NEW YORK.

IN an article entitled "The Diagnosis of the Invasion of Measles from a Study of the Exanthema as it Appears on the Buccal Mucous Membrane,"[1] I described for the first time a hitherto unobserved and pathognomonic appearance of the mucous membrane lining the cheeks and the upper and lower lips. This phenomenon had never to my knowledge been described before, and, as I said in my first article, its importance in enabling us to make a positive diagnosis of the invasion of measles cannot be overestimated. Inasmuch as this very valuable, and, as I think, original sign of the invasion of measles before even the appearance of the eruption has not received the notice it should have received, I have decided to describe it here at greater length, and add some illustrative cases.

This new phenomenon of measles appears only on the mucous membrane lining the cheeks and lips, and I have called this the buccal mucous membrane as strictly distinguished from the mucous membrane of the other regions of the mouth, such as that of the soft and hard palates and fauces, which do not concern us here. The eruption or phenomenon or sign which I wish to describe appears on the mucous membrane of the cheeks and lips fully twenty-four or forty-eight or even seventy-two hours before the appearance of the eruption or exanthema of the skin. It spreads and reaches its height just as the skin eruption has appeared and is spreading. It then fades. Thus we have a sort of cycle.

If we look in the mouth, at the invasion of measles there is nothing distinctive, especially about the eruption on the pharynx or on the soft and hard palates. The throat in the beginning is reddened: the fauces and the soft palate may be spotted, but this is also the case in many other affections, such as grippe, rotheln, ordinary catarrhal angina, scarlet fever. In the latter the redness is diffuse, not spotted. The first twenty-four or forty-eight hours of the invasion of measles is marked by a suffusion, slight or marked, of the eyes, and the conjunctiva at the nasal canthus is not only reddened but is distinctly redundant. There is at this stage a slight febrile movement. There may be a cough or some little sneezing. The mother has noticed nothing except that the infant or child has a slight fever. At this period the eruption has not made its appearance on the skin. In the vast number of cases there is no suggestion of an exanthema. In a few cases there may be an indistinct spotting around the lips and alæ nasi, but there is no eruption. In other cases nothing is seen on the face, but the back may show a few discrete spots.

The Mouth.—If we look into the mouth at this period we see in a strong light the usual redness of the fauces, perhaps not in all cases a few spots on the soft palate. On the mucous membrane lining the cheeks and lips (buccal mucous membrane) we see a distinct and pathognomonic eruption. This consists of small irregular spots of a bright red color, in the centre of each spot is the interesting sign to which I wish to call attention. In strong daylight we see a most minute bluish-white speck. These minute bluish-white specks in the centre of a reddish spot are absolutely pathognomonic of beginning measles. I have never met them elsewhere, and, when once seen, they are a certain forerunner of the skin exanthema. These bluish-white specks are sometimes so delicate that they can be seen only in a strong window light. No one has ever called attention to these bluish-white specks as a forerunner of the skin eruption. Their background is the irregular red spots referred to above. They cannot be mistaken for sprue, for they are not so deeply white nor are they as large as sprue spots, and sometimes we must, as I said, look sharply and evert the mucous membrane of the cheeks to find them. These bluish-white specks surrounded by a red area are found, as I said, on the mucous membrane of the cheeks and lips and not on the soft or hard palate. Sometimes only a few red spots exist with their central bluish points, a dozen or more, and again these whitish specks may cover the whole lining membrane of the cheeks and lips. If these bluish-white specks on a spotted background are at the height of their development, they never become as white and opaque as sprue spots, and therefore can be easily differentiated after having been once seen. Nor do they ever coalesce to become plaque-like in form. They always retain their punctate character. If the mouth has been washed these spots may have been rubbed off, and then the appearance is lost. I have noted, and, as I will show, diagnosticated these bluish-white specks on the inside of the cheeks and lips when the other symptoms of measles were so slight that other physicians have doubted the diagnosis. Subsequent investigation showed that the diagnosis was invariably followed by the exanthema.

The Cycle.—The phenomenon which I have described above is of especial value at the outset, before the appearance of the exanthema, and at the first appearance of the invading spots of the measles. As the exanthema on the skin appears and spreads, the eruption on the mucous membrane inside of the cheeks and lips becomes diffuse and the characters of a discrete eruption or spotting disappear, and we have an intense general redness which is simply dusted over with myriads of these bluish-white specks. This being so, it will be seen that this eruption of bluish-white specks on a spotted or red background is of the greatest value at the very outset of the disease, before the appearance of the eruption: also at the beginning and height of the skin eruption. When the skin eruption or exanthema is at its efflorescence, the buccal eruption begins to fade and gradually disappears, even while the exanthema is still out. In the later stages of the fading skin eruption the phenomena described above are no longer seen.

In demonstrating to physicians I have found that they will invariably tell me that other authors describe red spotting. I have admitted that this is so, but that my phenomenon is the bluish-white specks on the red spotted background. Henoch describes the eruption

[1] Archives of Pediatrics, December, 1896.

on the mucous membrane of the mouth thus: "Before the end of the second day you may observe, especially in robust children, on the hard and soft palates a diffuse redness spotted in places. More often the pale mucous membrane shows the so-called palate exanthema to a greater or less extent, punctate or star-shaped spots. These when distinctly visible may be considered a positive evidence of beginning measles."

It will be seen that the above does not mention the phenomenon described by me. Baginsky in his text-book speaks of a "spotted red appearance of the pharynx." Barthez and Rilliet simply mention a redness of the throat as preceding the eruption of the skin, quoting Heine and Despine. Bednar makes no mention of the eruption. Osler says in his text-book:[1] "Examination of the throat may show a reddish hyperæmia or in some instances a distinct punctiform rash. Occasionally this spreads over the whole mucous membrane of the mouth, with the exception of the tongue." Bohn[2] says: "Generally on the second or third day after the onset of the fever there appears on the slightly hyperæmic mucous membrane of the soft palate, the uvula, and the pillars of the fauces, small and large, somewhat indistinct dark spots, which later on spread over the buccal mucous membrane, at times on the hard palate, the lips, the gums. Not uncommonly they develop from a punctiform injection. They soon assume a distinct form and deeper coloring, and are distinctly circumscribed from the rest of the mucous membrane."

Here also we see no mention of the phenomena I have described.

Series of Cases.—I give now a series of cases in which the phenomena I describe were found; to illustrate the certainty of diagnosis, and the early diagnosis of the disease, simply by its aid alone. These patients appeared in my ambulatorium, were immediately isolated, and the exanthema was observed at the house of the patient.

Case I.—Annie R——, nine years old; ill three days. Exanthema just showing on the face and a few spots on the neck. Buccal mucous membrane shows full crop of my eruption. Measles subsequently confirmed.

Case II.—Ida W——, fourteen months old: first day ill. No eruption on the body; bluish-white spots in the mouth. Pyrexia; diagnosis, measles. Exanthema appeared three days after.

Case III.—Max P——, twenty-two months old. No eruption on any part of the body or face. Has my spots on mucous membrane of the cheeks and lips. Diagnosis, measles; confirmed by appearance of exanthema next day.

Case IV.—Harry Q——, six and one-half years old; as been ill with fever and cough two days. Absolutely no sign of an exanthema on any part of the body or face. Diagnosis, measles; confirmed by appearance of exanthema two days after.

Case V.—Rose L——, one year old; ill three days. Has no exanthema on any part of body or a suggestion of any. Has my spots on the mucous membrane of the cheeks and lips. Diagnosis, measles; confirmed by observation.

Case VI.—Birdie L——, five years old; has been ill three days. Has no exanthema; spots as described on the mucous membrane of the cheeks and lips. Diagnosis, measles; confirmed by subsequent study.

Case VII.—Sara F——, five and one-half years old: has been ill three days. No eruption on the face, slight suffusion of the eyes, a few indefinite spots on the back and abdomen. Buccal eruption brilliant. Diagnosis, measles. Exanthema appeared next day.

Case VIII.—Rose X——, three years of age. No eruption on the face: slight indication of an eruption on the back; febrile movement; bronchitis. My eruption on the mucous membrane of the cheeks and lips slight. Diagnosis, measles; confirmed by subsequent observation.

Case IX.—Sam J——, two years old; has been ill two days. Absolutely no exanthema. My eruption on the mucous membrane of the cheeks and lips. Diagnosis, measles: confirmed by subsequent observation of the exanthema.

Case X.—Sadie S——, two years and three months old; has been ill three days. Absolutely no eruption on the body; eyes red. Mucous membrane of the cheeks and lips shows my spots. Diagnosis, measles; confirmed by subsequent appearance of the exanthema.

Case XI.—Harry S——, seven years old; has been ill two days. No exanthema on any part of the body; eyes red. My spots on the mucous membrane lining the cheeks and lips. Diagnosis, measles; confirmed.

Case XII.—David H——, four years old; has been ill three days. Eyes red and suffused; no exanthema on the face; a few spots on the abdomen, upper part. Buccal mucous membrane shows my eruption. Diagnosis, measles. Exanthema came out next day.

Case XIII.—Sam K——, six years old. Exanthema has just appeared on the face: a few spots around the chin and some on the body. Has my eruption on the mucous membrane of the cheeks and lips. Diagnosis, measles; confirmed.

Case XIV.—Bessie L——, eleven months old; this is the third day of the disease. Has a very slight and discrete eruption on the face and body. Mucous membrane of the cheeks and lips shows my white specks on the red background. Diagnosis, measles: confirmed.

Case XV.—Joseph Q——, three years and four months old. There is no eruption on the face: a few indefinite spots on the upper part of the back. The mucous membrane of the cheeks and lips shows the eruption I have described. Diagnosis, measles; confirmed.

Case XVI.—Harry W——, four and one-half years old; has been ill forty-eight hours. There is suffusion of the eyes; a few spots show indefinitely around the eyes and alæ nasi. Mucous membrane of cheeks and lips shows my spots. Diagnosis, measles: confirmed.

The above cases are not picked cases, but are taken just as they came to me in my dispensary and observed by me and my assistants. I will say that it is absolutely necessary that the mouth should not have been washed. If this occurs, then the bluish-white specks will have been rubbed off and we simply have the irregular red spots left on the mucous membrane of the cheeks and lips; and these are not my eruption, and, as I will show, may occur in other affections, not especially with measles (aphthæ).

Analysis of the Cases.—It is most interesting to note that the exanthema of measles does not always appear first on the face, but that the back and upper part of the abdomen are sometimes the seat of the first indications of the measles exanthema. Again measles can be positively diagnosed in some cases fully two or three days before the appearance of the exanthema; in all cases positively twenty-four hours ahead of the exanthema, and without hesitation, if a few spots of the exanthema are present, no matter what the statements of the parents may be as to a previous attack of measles. And here let me add that it has often occurred to me that the parents would scout the idea of measles on my diagnosis, saying the child had had a previous attack. In these cases I have invariably had the parents tell me at a subsequent meeting that my diagnosis was correct. Of course the question always arises whether the first attack was one of real measles. I cannot stop over this question here.

The great value of this new sign of measles is shown in aborting epidemics of the disease in hospitals and

[1] 1892 edition. [2] Gerhardt's "Handbook."

institutions in which large numbers of children are housed. I have had occasion to see the test applied in an institution with which I am connected, with much satisfaction to the staff. In this hospital the question of the presence or absence of measles has often arisen since I have demonstrated my sign to the staff, and cases have been decided positively on its presence or absence. In a children's ward or in a large ambulatory clinic it can be readily understood how satisfactory it is both to the physician and patient, if a diagnosis of measles can be made before the appearance of the exanthema on any part of the body. Isolation is then practised at the earliest period.

Differential Diagnosis.—This sign of beginning measles is valuable not only in diagnosing the disease, but in sharply differentiating measles from a number of skin eruptions which in their onset simulate the measles rash very closely. Among these diseases we find rötheln, or German measles, forms of erythema multiforme, drug eruptions (quinine), scarlet fever. Again, beginning grippe is apt to simulate beginning measles. Aphthæ in the mouth are apt to be mistaken for measles eruption.

Rötheln: In rötheln we may have at most a slight reddening of the tonsils and the pillars of the fauces. The mucous membrane lining the cheeks and lips does not show the white specks, described above, on a reddened background. The mucous membrane has a normal pale pink hue. There may be a slight rise of temperature.

Erythema multiforme, or urticarious eruptions in infants or children, will often resemble very closely a measles rash, and mothers will send in great haste for the physician in order to decide the question of isolation from other children. It is also a serious matter, if the diagnosis of measles is once made, to keep the infant or child in the house, especially if we find that in a day or so the skin eruption has disappeared. In erythema or urticarious eruptions the buccal mucous membrane will decide the question at once. If the white specks on the red speckled background are absent, we may positively rule out measles.

Drug eruptions: I have seen the test applied to supposed cases of drug eruptions. In drug eruptions my sign is absent (cinchona, antipyrin).

Grippe: Beginning grippe simulates measles very closely. There are the suffusion of the eyes, coryza, and pyrexia. In grippe the mucous membrane covering the cheeks and lips has a normal pale pink hue.

Scarlet fever: The invasion of scarlet fever is marked by a redness of the fauces and also tonsillitis; there are a few red spots on the soft palate in most cases. The buccal mucous membrane has a pale normal hue; the measles signs are absent.

Aphthous stomatitis: The presence of small aphthæ in the mouth on the mucous membrane of the cheeks and lips is often associated with a slight febrile movement. They should not be mistaken for our sign. The spots of aphthæ are much larger and yellowish, and show ulcerations.

Examining for this Sign of Measles.—I have found that when asked about my sign of measles physicians would invariably say that they had seen it of old, when in reality closer questioning revealed the fact that they had reference to the red punctate appearance of the mucous membrane, which in itself is not my sign nor is it particularly diagnostic. They refer to the text-books, and reiterate that these spots are found on the soft and hard palates. I find in all these cases that physicians in reality have not seen or understood my sign of measles.

My sign can be seen only in very strong daylight falling from a window direct on the mucous membrane. It is then necessary to evert the mucous membrane covering the lips and cheeks, either with the fingers or by means of a spatula. One can then see by close study the infinitesimally minute bluish-white specks on a reddish punctate area in beginning measles, and on a more diffusely reddened background in advanced cases, which are absolutely pathognomonic of measles.

66 East Fifty-Eighth Street.

INSUFFICIENCY OF THE OCULAR MUSCLES.

By S. M. PAYNE, M.D.,

CONSULTING SURGEON TO HACKENSACK HOSPITAL; ASSISTANT SURGEON TO MANHATTAN EYE AND EAR HOSPITAL; ADJUNCT PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

On the 18th of May, 1893, I read before the ophthalmological section of the Academy of Medicine a paper on the insufficiency of the ocular muscles due to errors of refraction. I presented in that paper an original idea of mine, based upon the results of my work, and reported two hundred cases to prove the correctness of my conclusions. The especial point in the paper was to show that a vertical as well as a horizontal tendency for the eyes to deviate existed when the two eyes differed in refraction, and a horizontal tendency only when the refraction was the same. I have two especial objects in this paper: the one above mentioned, and the other to show that insufficiencies of the oblique muscles are due to a difference in the refraction of the two eyes, and that they cannot be found to exist when the refraction is the same. This last idea did not come to me until I had finished copying my cases for this report. I concluded to investigate and examined a few cases, and found three with oblique tendency, all of which were in patients whose eyes differed in refraction, and none in those whose eyes had the same refraction, though I found some difference in refraction in patients whose eyes showed no oblique tendency. I made my examinations with the Madox double prism. Dr. Eaton, of Portland, Ore., says that the oblique tendency exists frequently when it cannot be found with Madox prisms. As I am not familiar with his method of testing, I shall not attempt to explain it. He and others have written at some length on this subject, but it would take up too much space and time to include their views in this paper.

In my other paper I explained how the eyes turned downward as well as inward in accommodation, by the contraction of the inferior recti. I believed that the superior recti also acted in accommodation, but that, as the inferior recti were attached nearer to the cornea, they had the control of the eyes over the superior recti. We know that when we read a book or paper it is held below the horizontal plane of our eyes, and the nearer we hold the paper to us the farther it is below the horizontal plane. For instance, it is farther below the horizontal plane held thirteen inches or 3 D distant, than it is at twenty inches or 2 D distant. If we should have a hypermetropia in both eyes of 2 D, the tendency would be to converge to a point twenty inches from the eyes and downward in the same ratio. Again, if the hypermetropia should be 3 D in each eye, the tendency would be to a point thirteen inches and downward in the same ratio, provided the ciliary muscles had corrected the hypermetropia. If one eye had hypermetropia of 2 D, the tendency of that eye would be to converge to a point twenty inches distant and a little downward; and if the fellow eye had hypermetropia of 3 D, the tendency of that eye would be to a point thirteen inches distant and still farther below the horizontal plane.

In studying the cause of oblique insufficiency, I included the inferior obliques in the action of ac-

[1] Read before the ophthalmic section of the New York Academy of Medicine, May 17, 1897.

commodation, which embraces all the external ocular muscles supplied by the third nerve. While these muscles are contracting they have the control over the externi and superior obliques, which are then in a state of relaxation. If such a physiological action did not exist at the time of accommodation, the vertical meridians of the retina would be turned outward below and inward above from the vertical plane. Instead of the upper part of the eyes being turned outward by the inferior obliques, to retain their vertical plane in accommodation, the superior recti and inferior obliques counterbalance each other, while the superior obliques, which turn the eyes downward and outward, relax with the externi, and allow the inferior recti and interni to turn the eyes downward and inward, which keeps the eyes in their vertical plane.

In a case of hypermetropia the same in both eyes, the tendency is inward and downward and there is a torsion inward and downward the same with both eyes. If one eye has more hypermetropia than the fellow eye, and both are corrected by accommodation, the torsion downward and inward will be greater of the eye with the larger amount of hypermetropia, and consequently the vertical meridian of the retina will be thrown in a different plane, which will give the oblique insufficiency.

Myopic eyes are most always different in refraction and consequently cannot focus together, and for another reason the images are of different sizes on the retinæ. This causes a confusion, and as the eyes are without accommodation, or have less than is necessary for the required amount of convergence, the eye having the greater amount of myopia, or the poorer vision, is turned outward and downward by the externus and superior oblique, which are supplied by the fourth and sixth nerves, while the muscles supplied by the third nerve are in a state of relaxation. In this way that eye is turned below the plane of its fellow eye, and also has a torsion downward and outward. To explain more fully, I will take the obliques, the superior and inferior recti, in their paralyzed state. When the superior oblique of one eye is paralyzed, the vertical plane is turned inward below and outward above. A candle flame would then be tipped toward the nasal side, because the image of the upper part of the flame would be on the temporal side of the vertical meridian of the retina at the lower part of the macula, while the image of the base of the flame would be toward the nasal side of the vertical meridian of the retina at the upper part of the macula, which would turn the base of the flame outward. Again, the horizontal plane of the eye would be turned downward on the temporal side and upward on the nasal side. Place the double prisms base together, apices up and down, before the eye not affected, then place a card with a horizontal line in front of patient twelve inches or more distant, so that two parallel lines on a horizontal plane are seen with the eye behind the prisms. The eye affected would see one line between the two displaced lines. This middle line would run upward toward the temporal end and downward toward the nasal end.

When an eye has more hypermetropia than its fellow eye, the horizontal plane on its temporal half moves downward and on its nasal half upward more than does that of the fellow eye. The double prism being over the eye with less hypermetropia, the middle line seen with the greater hypermetropic eye would point the temporal end upward and the nasal end downward.

Paralysis of the superior rectus gives a torsion of the eye in the same direction as the superior oblique. Paralysis of the inferior rectus of an eye would allow the vertical torsion outward below and inward above, thus turning the lower half of the vertical plane outward, the temporal half of the horizontal plane upward, the upper half of the vertical plane inward, and the nasal half of the horizontal plane downward. The candle flame would tip outward above and inward at its base; the middle horizontal line with Madox prisms would turn downward to the temporal side and upward to the nasal side. Paralysis of the inferior oblique has the same torsion as has that of the inferior rectus.

In myopia the better eye fixes while the other turns downward and outward, and we have an entire relaxation of accommodation and a relaxation of the external ocular muscles supplied by the third nerve. This gives a torsion outward of the lower half of the vertical plane, upward of the temporal half of the horizontal plane, inward of the upper half of the vertical plane, and downward of the nasal half of the horizontal plane, thus tipping the candle flame outward above and inward below. The horizontal line is turned downward on the temporal side and upward on the nasal side, just as the paralysis of the inferior rectus or the inferior oblique.

When an eye that has more hypermetropia than its fellow eye fixes, the fellow eye turns or has a tendency to turn upward and inward, and the torsion will be inward below and outward above, just as the torsion of the greater hypermetropic eye would be if the fellow eye fixed. The greater hypermetropic eye fixes below the plane of the fellow eye, or the lesser hypermetropic eye fixes above the plane of the greater hypermetropic eye.

As I said before, the eye having the greater amount of myopia turns downward and outward by a relaxation of all the muscles supplied by the third nerve and a contraction of the external and superior oblique, and when that eye fixes the other eye turns upward and outward, still keeping the eye with the more myopia on a lower plane: but the torsion is inward above and outward below with either eye, just the opposite to hypermetropia, and consequently the candle is tipped outward above, and the horizontal line downward on temporal side and upward on the nasal side, just the reverse of hypermetropia. It is a very common thing to see a person with one eye turning downward and outward, and when that eye is made to fix the other eye turns upward and outward: the eye with the greater amount of myopia always keeping on a lower plane.

I do not hesitate to say that the right way to correct these tendencies to deviate is very simple and easy, but the wrong way will get one into a lot of trouble sooner or later. Theories that the muscle is attached too far forward or too near the cornea and must be set back by a tenotomy: or that it is too strong and either it must be cut or the muscle called the weaker muscle must be exercised by prisms to make it as strong as the opposing muscle; or to prescribe prisms to wear to make up the deficiency, are wrong in my opinion. I believe that some of our oculists who have worked on this line are becoming more conservative and depend more upon correcting the error of refraction. The compromise that some of them have made is that there are a pseudo and a true tendency to deviate—that is, if hypermetropia and esophoria exist, the amount of esophoria corrected by the correcting-glasses is the pseudo, and whatever remains is the true and should be removed by operation or prisms; also if exophoria exists with hypermetropia, it is true exophoria, and the scissors or prisms should be resorted to: that to give convex glasses, epecially the full correction, would increase the exophoria and consequently increase the asthenopia; that the amount of exophoria left when myopic eyes are corrected is the true, and should be corrected by tenotomy or prisms; that if esophoria exists with myopia, glasses may be prescribed for distant but not for near vision, as they would increase the esophoria and consequently the asthenopia.

Nothing is more perfectly adjusted than a pair of emmetropic eyes, free from paralysis, from paresis of their muscles, or from lesions. And there is no machine or organ that could lose its balance more easily. The controlling impulse is, first, to see as distinctly as possible, and secondly, to have an image of one object on each macula. Errors of refraction bring about all this disturbance in the correct balance of the external ocular muscles, and in my opinion an overcounterbalance can easily occur which would cause exophoria with hypermetropia and esophoria with myopia. The first impulse with hypermetropic eyes causes the ciliary muscles to contract, which brings about an involuntary contraction of the interni. Homonymous diplopia is prevented by a voluntary contraction of the externi. I believe it is an overvoluntary contraction of the externi in some cases that causes exophoria, or the line of central vision to move slightly too far outward. Correct the hypermetropia, and you remove the necessity of accommodation over and above what is required by emmetropic eye; the interni are then not forced to contract, and a voluntary contraction of the externi is not called for, and your exophoria with hypermetropia is corrected.

I believe that esophoria exists with myopia when there is an attempt to attain binocular single vision by a voluntary contraction of the interni; this voluntary contraction is overdone, and brings the line of vision beyond the line of vision of the other eye, just as a person running is unable to stop on a line.

If prisms are prescribed for esophoria with hypermetropia, they cause a voluntary contraction of the interni to overcome the amount of the prisms plus the involuntary contraction of the interni induced by contraction of the ciliary muscles. You will find the esophoria about the same with the prisms on after a few days' or weeks' wearing as it was on first examination before prisms were prescribed. If prisms are prescribed, with the hypermetropic correction exophoria is produced to the amount of the prisms, and is corrected by a voluntary contraction of the interni, since the esophoria was corrected by the correcting glasses. In myopia with exophoria the same voluntary contraction exists to overcome the prisms, in addition to the muscle action due to the myopia. If the myopia is different in the two eyes, the eye with more myopia will turn outward and downward in spite of all the prisms worn in front of the eye, as it is impossible for the object to be seen as one by throwing the image on the macula of the turned eye by a prism, since the images are different in size and the eye turns out just as much more to escape diplopia. If the prisms are prescribed with the correcting-glasses, esophoria is produced, because the glasses correct the exophoria, and the prisms, base in, make esophoria, which is corrected by the same amount of divergence that existed before the correcting-glasses were worn.

Prism exercises are resorted to with the object of increasing the strength of the weak muscle. If such a thing is possible it is not necessary, since the muscle is not too weak, nor is the opposing muscle too strong, but there is simply an overcontraction, which will be shown by a number of cases I shall describe at the close of this paper. It is bad practice, not only in that it does no good but also for the reason that it does harm. Nervous patients, women and children, for instance, it sends home exhausted bodily, and nothing short of a few hours in bed recuperates them. Several years ago I tried the prism practice on a few patients, and on their next visit they would tell me how exhausted they were, and that they had to go to bed for the rest of the day.

Partial tenotomies are misleading to both physician and patient, inasmuch as the eyes have an absolute rest for two or three weeks after the operation, which causes the disappearance of the asthenopia. Such patients would not dare use their eyes so long as they could see any blood under the conjunctiva. It is still more misleading when glasses are prescribed just after the operation, for, if they are the right glasses and no effect has been produced by the tenotomy, the operator never finds out that the tenotomy did not help to cure the asthenopia.

When by the operation an effect has been attained in removing entirely or partly the tendency to deviate, the surgeon and patient meet with a more serious difficulty. This difficulty is in retaining binocular single vision, more especially if the patient looks in the direction of the cut muscle, which has lost its ability to move the eye as far in that direction as the associated muscle can move the fellow eye in the same direction; consequently the eye with the cut muscle lags behind its fellow eye on account of the muscle being set farther back than its normal attachment. The effect is just the same if only part of the tendency to deviate is corrected by the tenotomy. That is, if one cuts for ten degrees of esophoria and still has five degrees of it left, when the patient looks toward the cut muscle he has exophoria or crossed diplopia. If an externus is cut for exophoria and only part of the exophoria is corrected, the patient has esophoria or homonymous diplopia when looking in the direction of the cut muscle. Not alone is the associated movement of the eyes disturbed, but also convergence in accommodation. If it is the internus which is cut, that eye does not come up to the same line of focus with its fellow eye; and if it is the externus, that eye moves beyond the line of focus with the other eye. Hypermetropic glasses give some relief, so far as to take the strain from the ciliary muscles. Myopic glasses give relief so far as to induce convergence in accommodation and take the strain from the cut externus. But these cases are never entirely relieved by glasses. If the muscle can be recut and brought forward to its original attachment, then the glasses will complete the cure, just as they would have done if the muscle had never been cut.

In order to remove the vertical tendency to deviate and also the oblique, correct the difference of refraction between the two eyes. To remove the horizontal tendency to deviate along with the vertical it may be necessary to correct the total amount of hypermetropia in both eyes, but usually this is not necessary if the uncorrected amount is small and the same. This then gives the same amount of work for the ciliary muscles to do, and the same amount of work for the external ocular muscles, which are associated with the ciliary muscles. The eyes then converge the same, and the line of vision is the same below the horizontal plane in convergence.

Manifest hypermetropia varies according to the way the examination is made. I remember finding in a patient 4 D in both eyes at once, when only a $\frac{1}{4}$ D had been found testing each eye separately. In another patient, who was wearing +0.50, examination showed no manifest hypermetropia with each eye separately, but with +1.5 D over both eyes the vision was $\frac{20}{15}$, and more distinct than without.

My method of finding manifest hypermetropia is to place the next stronger glass in front of the eye under examination before removing the one already in front of the eye, thus preventing the eye from accommodating to the amount of the glass removed, and to continue on in this way until the eye refuses a glass. I then place the next stronger and remove the glass which was refused. In a few seconds I replace the latter and then remove the stronger glass, and the chances are about equal that the glass first refused will be accepted. I then go on in this way until the eye refuses to accept the next weaker glass after the stronger has been removed.

After getting this result in each eye, I place the combination before both and work them up together by increasing the combination the same and in the same way as in each eye separately. It depends largely upon the intelligence of the patient as to the amount of manifest hypermetropia with both eyes together, over the amount of each tested separately. The intellectual class accepts a small amount of increase if any, while the most unintellectual are as a class as much disturbed over a blind in front of one eye as though it were a mosquito or bee flying around one eye. After you have explained why you have one eye covered they become a little more quiet, but accommodate to their utmost to see as much with one eye as they did with both. This would probably cause them to refuse the weakest convex glass, when they would accept a strong convex glass by giving them their natural way of seeing, both eyes together. Some patients refuse to show much manifest hypermetropia in any way you examine for the distance, when they are positively unable to read the diamond type or see it with difficulty, and often under a strain, with their manifest correction. In a case like this increase the strength of the manifest glass until they can read the diamond type easily. When you have arrived at this combination of glasses, give them ten minutes' time to read with it, and if there is no drawing or smarting feeling of the eyes, that is, if the eyes feel perfectly comfortable and easy, you may be sure that they have at least that much hypermetropia. When these glasses are prescribed, the more they are used for the near the sooner they will become all right for the distant wearing also. As patients more often complain of their eyes for near work, and the majority of them have to earn their living by near work, and children more often complain only of their eyes while studying, it is more important to give the correction best suited for the near. The difference between the manifest for the near and for the distant soon becomes the manifest for the distant. Your patients should be made as intelligent as possible about wearing their glasses, or they will soon become disgusted with the blurring of those for the distant and refuse to wear them any longer. If they are intelligent enough to understand the reason why there is a blurring at the distant, and why they should wear glasses for the distant as much as possible, they will do so. You may compromise with them by letting them take their glasses off in the street, but must insist that they keep them on while they are indoors, as most of the things they want to see while at work are within a few feet of them, which requires a small amount of accommodation. In this way they would have their glasses on almost the entire day and would soon accept them also for the street. The majority of patients who have prescribed for them the manifest of each eye for the distant have to change their glasses from time to time for stronger ones, which in the end gives them much more trouble and expense for glasses and examinations.

My plan of examination is to use the ophthalmoscope first, for a foundation. If pains are taken in this examination, the total or very nearly the total amount of hypermetropia can be found. When I turn on a convex glass that blurs the retinal vessels, I continue to look with it, and if more hypermetropia exists the patient soon relaxes the accommodation, as he is looking into a dark space with the eye not under examination, while the ophthalmoscope is too near the eye under examination for accommodation. An estimate can be made also of the astigmatism and its axis, if any exists. My second examination is made with the ophthalmometer. If it shows astigmatism, I know whether it is myopic or hypermetropic, as my ophthalmoscope has given me that information. I consider the primary position as being at the axis where the mires begin to lap. In this position, should there be myopic astigmatism, the long pointer indicates the axis of the myopic glass on the test frame; and if hypermetropic, the two short pointers which are on the mires indicate the axis of the convex cylinders on the test frame. That is, the mires lap up to the shortest curvature of the cornea. When plus and minus marks are placed before their respective hypermetropic and myopic astigmatism and the right axis for the glass is ascertained, the matter is very much simplified. The third step in the examination is to see what the tendency to deviate is, and the amount. If it is only a horizontal tendency, I expect to see the same error of refraction in the two eyes. If a vertical tendency exists alone, or together with a horizontal tendency, I expect to find that one eye has more error of refraction than the fellow eye. The fourth step of examination is with the test lenses, as before described. Lastly I make a note of the amount of the tendency to deviate with the glasses on. Thus having made the examination with the test lenses the last part of the examination, you are intelligent as to the result you ought to get with the test lenses and thus avoid the use of atropine in about ninety-five per cent. of cases. In permanent squint one eye is amblyopic and should have an absolute correction to correct the squint; it should be examined and have glasses prescribed under atropine.

In alternating squint neither eye is amblyopic and it takes less inducement to make the eyes see together, and it is seldom necessary to use atropine; besides, they usually have the same error of refraction.

Another suggestion I will make about manifest hypermetropia. In compound hypermetropic astigmatism, with one eye at a time under examination, both glasses together are often refused, while either glass separately improves the vision, and with both eyes together a sphero-cylindrical is accepted over each eye by using on the cylindrical combination and then with both eyes placing the same strength of spherical behind each cylinder and gradually increasing the strength until the maximum manifest is found. Again, when hypermetropia exists in both eyes with astigmatism in only one, the eye having the astigmatism refuses the spherical while the cylinder is on the eye. In this way a mistake is too often made by giving the spherical for one eye and a cylinder for the other. Instead of prescribing the above combination, place it in a frame before the eyes and then place a weak spherical along with the cylindrical and increase its strength up to the strength of the other spherical. As the strength of the glass approaches the strength of the other spherical, if the comfort of the eyes increases and the vision becomes more steady, you may be sure that you are not overcorrecting the hypermetropia in the astigmatic eye.

In compound hypermetropic astigmatism, differing in the two eyes, the difference is in the astigmatism, while the spherical part is the same in almost every case.

In myopia I always correct the whole amount in each eye, and have all patients under the age of presbyopia wear the full correction for near work as well as for distant, except in maximum degrees of myopia, say from 15 D to 20 D, when it seems impossible for them to read or do near work without a weaker glass. When this reduction is made I find that about 3 D has to be taken off the full correction. This amount of reduction brings the far point to thirteen inches. The patient can then see at thirteen inches without accommodation. When the myopia then is either 15, 16, 17, 18, 19, or 20 D, the reading glasses should be 12, 13, 14, 15, 16, or 17 D.

Such strong concave glasses would act as two prisms, bases in, as the rays of light coming from a point thirteen inches in front of the eyes diverge toward each

pupil and fall on the nasal side of the centre of each glass, provided the centres of the glasses are directly in front of each pupil. This would make up for the deficiency in convergence due to weak accommodation.

When the myopia is of a less degree than above mentioned, the total correction can be worn for both far and near unless the patient has approached too near the presbyopic age.

Myopia increases when an undercorrection is given for all distances and also when full correction is given for the distant and undercorrection for the near, under the presbyopic age, in just the same way as though no glasses were worn.

A positive proof of the above statement is from the large number of such patients who have been under my observation; their statement as to the doctor's examination and ordering of glasses; my measurement of their glasses; and my measurement of their refraction, showing that stronger glasses were required than their strongest glasses, which were intended for their full correction (or their distant glasses).

I remember only two cases in which when I gave the full correction to be worn for both far and near the myopia increased, and in one of the cases I prescribed the glasses under atropine, with which the myopia was 0.25 D less than without the atropine. The other was one of my first cases when I began ophthalmology. At that time I may not have given the exact or full correction. By giving the full correction to be worn all the time, the power of convergence is restored by the necessary action of the ciliary muscles for the near point, as the interni are stimulated to contract in the same proportion as is the ciliary muscle. Only the full correction restores entirely the power of accommodation and convergence, which does away with the tendency to divergence. When you give a partial correction for the near point you partly correct the tendency to divergence, or the tendency may remain just the same, as the inability to retain binocular single vision causes one eye to seek refuge far enough outward to avoid double vision, just as before any glasses were worn. It is evident to me that it is the tendency to deviate outward, or a deviation outward, that causes an increase of myopia, and for the same reason I believe that the starting-point of acquired myopia is the tendency to divergence in hypermetropia, which I attempted to explain while on the subject of hypermetropia.

When the myopia is different in the two eyes and the same strength of glass is given for both eyes, the point at which accommodation begins in one eye is different from that in the fellow eye. While focussing with the less myopic eye at the more distant point, the object appears blurred to the more myopic eye and looks larger. While the more myopic eye with its partial correction is focussing at a certain point, the less myopic eye, which has the same strength of glass, would see the object blurred and smaller. In either case, the more nearly the error is corrected the more distinct the object becomes, and the more the discarded eye is forced to recognize the object. This forces both eyes to try to work, though it is impossible for them to work together. It is not so bad for the patient if a plain glass is prescribed for the more myopic eye and a correction is given for the other eye, as the more myopic has become accustomed to discarding the image, and also as the difference of focus, distinctness, and size of the object have been increased by correcting the better eye.

Notwithstanding this there is a disturbance by the uncorrected eye in accommodation, for the nearer the object approaches the more distinct it becomes, and if the eye is not very near sighted there will be a point where it will be obliged to recognize the object.

In prescribing the full correction in myopia, I advise patients not to use their eyes for the near any more at first than they are obliged to do, and they will find that they will be able to use them longer each day, as the strength of the ciliary muscle will gradually recover. I have written up five hundred and forty cases for this report, but could have only five hundred and fourteen in the table which will be found at the conclusion of this paper. In the remaining twenty-six either the patient had been wearing prisms or some muscle had been crippled by a tenotomy, and consequently they could not be classed with the other cases. This fact was not noticed until they were written up and numbered.

I will present thirty-three cases selected from the five hunderd and forty, giving only my examination.

Case XVIII.—Miss K——, aged eighteen years. August 9, 1890. Old glasses are: R. +0.50 D prism 3 base in; L. +0.75 D +0.25 D ax. 90°. Reading small print one line becomes two, one above the other. R. V. = $\frac{20}{15}$; $\frac{20}{10}$ with + 1 D. L. V. = $\frac{20}{50}$; $\frac{20}{20}$ + with +1 D ⌒ +1 D ax. 95°. Hypophoria, L. ¾°. Exophoria, 4°. With the above correction, orthophoria.

Case XXX.—Mr. R——, aged twenty-eight years. October 2, 1890. R. V. = $\frac{5}{200}$; $\frac{20}{15}$ with −6 D ⌒ −0.75 D ax. 135°. L. V. = $\frac{20}{200}$; $\frac{20}{15}$ with −6 D. Hypophoria, R. 1°. Exophoria, 3°. With above correction, orthophoria.

Case XXXI.—Miss D——, aged thirty-six years. October 3, 1890. Under the care of a neurologist for nervousness. She is wearing +4 D. R. V. = $\frac{20}{100}$, $\frac{20}{40}$ with +5 D ax. 75°. L. V. = $\frac{20}{100}$; $\frac{20}{40}$ with +3.5 D ax. 105°. Hyperphoria, R. 2°. With above glasses, hyperphoria, ½°.

Case LIII.—Mrs. T——, aged sixty-six years. November 20, 1890. R. V. = $\frac{20}{20}$ with +4.50 D. L. V. = $\frac{20}{20}$ with +5 D. Hypophoria, L. 3°. Exophoria, 6°. With above glasses, orthophoria.

Case LIV.—Mrs. O——, aged twenty-nine years. November 24, 1890. R. V. = $\frac{20}{20}$; $\frac{20}{15}$ with +0.50 D ax. 90°. L. V. = $\frac{20}{20}$; $\frac{20}{15}$ with +0.50 D ax. 90°. Next day atropine three times. R. V. = $\frac{20}{100}$; $\frac{20}{20}$ with +1.75 D. L. V. = $\frac{20}{100}$; $\frac{20}{20}$ with +1.75 D. Esophoria, 16°. With red glass, homonymous diplopia, 16°. With 0.75 D, esophoria, 3°. Ordered +1.150 D.

January 3, 1893. Over two years since the 1.50 D was ordered. With 1.50 D, esophoria, 6°; with 1.75 D, esophoria, 4°; with 2 D, esophoria, 0. V. = $\frac{20}{15}$ with +2 D, and more comfortable than with any other glass ordered. The esophoria 6° with the +1.50 D would be called the true esophoria by some of our distinguished oculists, because that much of the 16° was not corrected by wearing the +1.50 D.

Case LX.—Miss McL——, aged forty-eight years. December 9, 1890. R. V. = $\frac{20}{15}$; E. L. V. = $\frac{20}{50}$ −; $\frac{20}{30}$ with −0.75 D ax. 30°. Red glass showed crossed diplopia, 14°, and vertical diplopia, 8°. With red glass and correction for the left eye a pink candle flame is seen and she cannot make diplopia by trying.

Case C.—Miss C——, aged twenty-six years. March 6, 1891. Has 0.75 D, axis 90°, both. R. V. = $\frac{20}{50}$ +; $\frac{20}{15}$ with −0.50 D ⌒ +1.50 D ax. 75°. L. V. = $\frac{20}{100}$; $\frac{20}{15}$ − with −0.50 D ⌒ +2 D ax. 105°. Hypophoria, left ½°. With above correction, orthophoria.

February 15, 1894. Her eyes feel as though something was in them. Could make no change of the glasses and with them orthophoria.

Case XIII.—Mrs. H——, aged fifty-three years. May 12, 1891. R. V. = $\frac{20}{20}$; $\frac{20}{15}$ with +0.75 D. L. V. = $\frac{20}{30}$ +; $\frac{20}{15}$ with +1 D ax. 120°. Hypophoria, L. 1°. With above combination, orthophoria.

Case CXXXII.—Mrs. K——, aged twenty-seven years. May 14, 1891. R. V. = $\frac{4}{200}$; $\frac{20}{20}$ with −8 D. L. V. = $\frac{4}{200}$; $\frac{20}{20}$ with −8 D. Red glass over one eye, candle flame crossed 3° and level. With above correction and red glass, only one light.

Case CXXXVIII.—Mrs. William H——, aged forty-eight years. June 20, 1891. London, England. R. V.= $\frac{20}{200}$; $\frac{20}{100}$ with −9 D. L. V.= $\frac{20}{15}$; E. Hypophoria, R. 4°. With −9 D over right eye and a red glass the lights are level. Ordered R. −9 D, L. plain glass.

June 14, 1892. One year later less six days. She says that the glasses cured her headaches.

Case CLXX.—October 6, 1891. Miss B——, aged fourteen years. R. V.= $\frac{20}{20}$; $\frac{20}{15}$ with +0.75 D. L. V. = $\frac{20}{30}$; $\frac{20}{15}$ with +0.75 D. Esophoria, 9°. No vertical tendency. Ophthalmoscope, +1.25 D.

November 11, 1892. Under atropine. R. V.= $\frac{20}{20}$; $\frac{20}{15}$ with +1.25 D. L. V.= $\frac{20}{30}$; $\frac{20}{15}$ with +1.25 D. Ordered the latter.

September 30, 1893. With her glasses +1.25 D, orthophoria.

Case CLXXIV.—October 10, 1894. S. G——, aged thirty-five years. R. V.= $\frac{20}{200}$; $\frac{20}{30}$ with −6 D. L. V. = $\frac{12}{200}$; $\frac{20}{30}$ with −9 D. With red glass over right eye the red flame is seen to the left and below, showing that the left eye is turning downward and outward. With the correction the lights are level but slightly crossed.

Case CCXXXVIII.—February 24, 1892. Miss M——, aged twenty-one years. R. V.= $\frac{20}{30}$; $\frac{20}{20}$ with −0.75 D ax. 165°. L. V.= $\frac{20}{30}$; $\frac{20}{20}$ with −0.50 D ax. 180°. Exophoria, 12. Hyperphoria, 1°. Crossed diplopia with red glass, which was corrected by the above combination and red glass remaining in front of one eye.

Case CCLXXXIII.—July 12, 1892. F. W. B——, aged three years. R. V.= $\frac{20}{40}$; $\frac{20}{30}$ with +3 D ax. 90° ⊂ −0.75 D ax. 180°. L. V. = $\frac{20}{20}$; E. Esophoria, 2°. Hyperphoria, R. ½°. Corrected with the above.

Case CCCXX.—October 13, 1892. Miss W——, aged forty years. Old glasses are 2 D. R. V.= $\frac{3}{200}$; $\frac{20}{40}$—with −9 D ⊂ −0.75 D ax. 180°. L. V.= $\frac{20}{30}$; $\frac{20}{15}$ +with +1.25 D ax. 90°. With red glass crossed and vertical diplopia, the right eye turning downward and outward. With red glass and the correcting-glasses, the lights moved into one light, which made the eyes comfortable. The above glasses were ordered for distance. For reading R. −8 D ⊂ −0.75 D ax. 180°. L. 1 D ⊃ +1.25 D ax. 90°.

Case CCII.—December 3, 1891. William N——, aged twenty-three years. R. V.= $\frac{20}{30}$+; $\frac{20}{20}$ with −0.75 D ax. 180°. L. V.= $\frac{20}{20}$; better with −0.25 D ax. 180°.

December 5, 1891. Under homatropine. Esophoria, 30°. Hypophoria, R. 2°. R. V.= $\frac{20}{200}$; $\frac{20}{30}$ +with +2.25 D ⊃ +1.25 D ax. 90°. L. V.= $\frac{20}{20}$; $\frac{20}{20}$ +with +1.50 D. With the last glasses, orthophoria.

Case CCXII.—December 28, 1891. Miss K——, aged seventeen years. R. V.= $\frac{20}{30}$ with +1.50 D ⊃ +1.25 D ax. 90°. L. V.= $\frac{20}{30}$ with +1.50 D ⊃ +1.25 D ax. 90°. Esophoria, 9°. No vertical tendency to deviate. With above correction, orthophoria.

Case CCXVI.—Miss W——, aged twenty-seven years. R. V.= $\frac{6}{200}$; $\frac{20}{30}$ with −9 D ⊃ −1.50 D ax. 160°. L. V.= $\frac{6}{200}$; $\frac{20}{30}$ with −7 D ⊂ −1.50 D ax. 15°. Hypophoria, R. 1°. Exophoria, 2°. With above correction, orthophoria.

Case CCCXLVI.—January 9, 1893. F. A. D——, aged twenty-seven years. R. V.= $\frac{20}{200}$; $\frac{20}{20}$ +with −2 D. L. V.= $\frac{20}{200}$; $\frac{20}{15}$ —with −1 D. With red glass over the left eye the red light is to the right and below, showing a turning downward and outward of the right or more myopic eye. Diplopia corrected by the glasses.

Case CCCLIII.—Mrs. F. M——, aged twenty-four years. R. V.= $\frac{8}{200}$; $\frac{20}{20}$ with −4 D. L. V.= $\frac{12}{200}$; $\frac{20}{20}$ with −3 D. Exotropia, 23°. Hypertropia, R. 7°. Second examination showed R. V.= $\frac{20}{15}$ with −3.50 D. L. V.= $\frac{20}{15}$ with −2.50 D. With last, above orthophoria and perfectly comfortable.

Case CCCLIX.—February 27, 1893. Mrs. E. O——, aged thirty-five years. R. V.= $\frac{20}{30}$ + with −5 D ax. 30° ⊂ +1.50 D. L. V.= $\frac{20}{30}$ + with −0.50 D ax. 150°. With red glass, right eye turns outward 3° and downward 1°. Corrected by the above glasses.

Case CCCLXXXVII.—May 15, 1893. Miss E. Z——, aged twenty years. R. V.= $\frac{20}{30}$; $\frac{20}{20}$+with +3 D. L. V. = $\frac{20}{30}$; $\frac{20}{20}$ + with +3 D. Esophoria, 14°; with +3 D, only 4°. Homonymous diplopia with red glass. Binocular single vision, with +3 D and red glass. No vertical tendency to deviate.

Case CCCCI.—June 26, 1893. Mrs. C. C——, aged thirty-four years. R. V.= $\frac{20}{50}$; $\frac{20}{20}$ + with 2 D ⊂ +1.25 D ax. 60°. L. V.= $\frac{20}{50}$; $\frac{20}{20}$ +with 2 D ⊂ +175 D ax. 120°. Ordered. Esophoria, 28°; with the above glasses, 18°.

July 19, 1893. Has worn the glasses all the time. Cannot see to read or sew and can hardly see to eat. Esophoria, 8° with her glasses and esotropia, 7° with red glass. V.= $\frac{20}{15}$ with +2 D. Ordered the +2 D increase over her glasses. With this combination: R. +4 D ⊂ +1.25 D ax. 60°; L. + 4 D ⊂ + 1.75 D ax. 120°. Her eyes have no tendency to deviate.

Case CCCCXIX.—October 16, 1893. W. G. S——, aged thirty-two years. Old glasses are −7 D. R. V. = $\frac{5}{200}$; $\frac{20}{50}$ with −7 D. L. V.= $\frac{5}{200}$; $\frac{20}{100}$ with −7 D. R. V.= $\frac{20}{15}$—; with −10 D ⊂ − 1 D ax. 180. L. V. = $\frac{20}{15}$—; with −10 D ⊂ −0.50 D ax. 180°. Ordered. Hypophoria, R. 1°. With the last glasses, hypophoria none or orthophoria.

Case CCCCLI.—January 21, 1894. Mrs. J. M. H——, aged sixty-five years. R. V.= $\frac{20}{100}$; $\frac{20}{30}$ with +2.75 D. L. V.= $\frac{20}{100}$; $\frac{20}{15}$ with +2 D. Hyperesophoria, R. With above glasses, orthophoria.

Case CCCCLIII.—January 29, 1894. A. B——, aged seventeen years. R. V.= $\frac{7}{200}$; $\frac{20}{30}$ —with −8 D ⊂ −0.75 D ax. 180°. L. V.= $\frac{7}{200}$; $\frac{20}{30}$ with −8 D ⊂ −0.50 D ax. 180°. Hypoexotropia, R. With red glass, no hypophoria. Exophoria, 4°. Corrected by the above, orthophoria.

Case CCCCLXVI.—April 2, 1894. Mrs. A. P. S——, aged twenty-four years. R. V.= $\frac{20}{100}$; $\frac{20}{20}$ with −3 D ax. 15°. L. V.= $\frac{20}{200}$; $\frac{20}{30}$ + with −3 D ⊂ −2.50 D ax. 165°. Red glass over left eye shows the left eye to turn downward and outward. With the above glasses and the red glass only one light is seen, and that a pink showing a mixing of the red and white light.

Case CCCCLXXVII.—June 5, 1894. O. K——, Jr., aged thirty-six years. R. V.= $\frac{20}{15}$; $\frac{20}{15}$ with + 2 D. L. V.= $\frac{20}{20}$; $\frac{20}{15}$ with +3 D. Hyperphoria, L. ½°. Esophoria, 1°. With the above corrected, orthophoria.

Case DXV.—January 15, 1895. Miss M. C——, aged eighteen years. R. V.= $\frac{20}{70}$; $\frac{20}{15}$ with −1.50 D ax. 90°. L. V.= $\frac{20}{70}$; $\frac{20}{15}$ with −0.50 D ⊂ −1.50 D ax. 90°. Hyperphoria, L. ½°; with above glasses, orthophoria.

Case DXVIII.—January 19, 1895. Miss A. A. G——, aged forty-one years. R. V.= $\frac{20}{40}$; $\frac{20}{20}$ with + 1.25 D ax. 90°. L. V. = $\frac{20}{30}$ W−8 D. Red glass over left eye makes a large red globe of the candle flame, and the right eye sees the flame in lower part of globe, which is a tendency downward of the left eye. With the above correction the eyes feel rested and the two lights go into one.

Case DXXVI.—February 12, 1895. Rev. G. V——, aged thirty-three years. Has R. −1.50 D. Left, plain glass. R. V.= $\frac{5}{200}$; $\frac{20}{15}$ with −5.50 D ⊂ −0.25 D ax. 105°. L. V.= $\frac{20}{15}$; $\frac{20}{15}$ + with − 0.25 D ax. 60°. With above correction no hyperphoria but still an exophoria of 12°, and a torsion inward of the left eye in accommodation at fifteen inches, while the right eye remained fixed, having no accommodation. This was made with the Madox double prisms, bases together, showing the middle of the three lines running obliquely downward to the left.

Case DXXXV.—F. G——, aged twenty-nine years.

Old glasses: R. 0.50 D; L. 1 D ax. 180°. R. V. $= \frac{20}{15}; \frac{20}{10}$ with +0.75 D. L. V. $= \frac{20}{20}; \frac{20}{15}$ + with −0.50 D. Hyperphoria, L. ½°. Esophoria, 1°. Corrected by the glasses.

CASE DXL.—Miss E. T——, aged twenty-two years. R. V. $= \frac{20}{20}; \frac{20}{15}$ with +0.75 D ax. 90°. L. V. $= \frac{20}{30}; \frac{20}{15}$ with +0.50 D ax. 90° ○ −1 D ax. 180°. Hypophoria, L. 3°. Esophoria, 3°. With Madox double prisms the middle line is oblique and half corrected by the above glasses.

Man's Ancestors.—We can point now to the long-since extinct ancestors of the lowest vertebrates; we are able to introduce all the reptiles, the birds, and the mammals to their primitive prototypes. In the mammals particularly, gap after gap which seemed to separate species and genera and orders has been successfully spanned by the discovery of intermediate forms; and we have now the genealogical types of the deer, musk, horse, tapir, rhinoceros, cat, lemur, monkey, and many others; and yet, as regards the pedigree of man, we are still in the dark. Professor Huxley's impressive words still hold. Paleontology sheds no light on man's origin: for, "so far as that light is bright, it shows him substantially as he is now, and when it grows dim it permits us to see no sign that he was other than he is now." Missing links to connect the human species with the demonstrated evolutionary law of the world of life and matter are quoted, of course: but it seems wellnigh impossible to prove that an alleged link is anything more than an extreme instance of some particular type. And it is pretty certain that if missing links exist, they must be sought for in a period much farther back than we are at present able to explore.—*Science Siftings.*

STUDIES ON GANGLION CELLS: A PRELIMINARY COMMUNICATION.[1]

By JAMES EWING, A.M., M.D.,

CLARK FELLOW IN PATHOLOGY, [illegible] FACULTY, NEW YORK.

ALTHOUGH, during the past decade, a large and rapidly increasing number of observations have fully established the superiority in many respects of Nissl's method of staining nerve cells, and some facts have been proven and many more claims made regarding the significance of the changes demonstrated by the new stain, it has not yet been made possible fully to interpret the great variety of morphological appearances of the ganglion cell revealed by Nissl's technics.

In nearly every detail of the subject there has been great or irreconcilable difference of opinion among recognized authorities. A large number of modifications of Nissl's original procedure have been suggested, and their value and reliability variously estimated. The lack of uniformity in the effects of many fixing-agents employed has been a serious obstacle in the way of separating artifacts from pathological alterations. The normal histology of the ganglion cell in different regions of the central nervous system has not been fully determined, and we are still far from a knowledge of its ultimate structure, although much progress has been recognized in this department during the last few months. In 1895 practically nothing was known about post-mortem alterations in ganglion cells. In the group of infectious diseases, a series of cellular changes has been described by some observers, consisting principally in various grades of chromatolysis, while other investigators have failed to find these changes or have denied their importance. The cellular lesions induced by fatal doses of mineral and vegetable poisons have been described as characteristic and uniform by some writers, while others have failed to regard these appearances as specific. Probably the specific character of the peculiar form of degeneration of ganglion cells following experimental section of peripheral filaments, and consisting of central chromatolysis and eccentricity of nucleus, has been established beyond a doubt; but the observations are as yet entirely inadequate to warrant the statement that wherever such forms of degeneration are seen these cells have suffered a loss of function of their axis-cylinder processes.

Attempts have been made to distinguish this secondary degeneration of ganglion cells from the primary changes induced by circulating toxic agents, but the differences between these sets of changes have never been intelligently described, so far as the writer can find.

The morphological changes resulting from activity or fatigue of ganglion cells have formed the subject of several very painstaking studies, but to-day no definite morphological appearances can be regarded as indicating rest, activity, or fatigue on the part of the ganglion cell.

Profound changes in the anterior horn cells of the lumbar cord have several times been noted after ligature of the abdominal aorta in animals, but somewhat similar changes have been found under conditions apparently very dissimilar. Moreover, the whole subject of the importance of chromatolysis in the pathology of the ganglion cell received a serious blow from the evidence recently furnished that this condition may be extreme in still functionating cells (Goldscheider and Flatau). In hibernating animals also the chromophilic bodies have been found to disappear (Levi).

The wide field opened up by these recent results of experimental pathology for the application of Nissl's

[1] Read before the New York Pathological Society, February 9, 1898.

method in the study of the central nervous system in general diseases has led the writer to undertake the systematic examination of the central nervous system in a series of cases, representing a variety of conditions, and coming to autopsy at Roosevelt Hospital during the past two and one-half years. These cases may be grouped as follows:

Infectious diseases: Lobar pneumonia, 3; typhoid fever, 3; acute purulent meningitis, 3; tetanus, 1; hydrophobia, 1; pernicious malaria, 1; empyema, 1; peritonitis, 2; septicæmia, 2; pyæmia, 1.

Auto-intoxication: Uræmia, 7; eclampsia, 3; sunstroke, 3; epilepsy, 2; diabetic coma, 1; pernicious anæmia, 3; leukæmia, 2; asphyxia, 1.

Acute poisoning: Alcoholism, 3; morphinism, 2; carbolic-acid poisoning, 2; hydrochloric-acid poisoning, 1.

Mechanical disturbance of cerebral circulation: Hemorrhagic pachymeningitis, 3, subdural hemorrhage, 3; acute ependymitis, 1; thrombosis of basilar artery, 1, intraventricular hemorrhage, 1.

Miscellaneous: Aneurism of aorta, 1; rupture of viscera, 2; tabes and carcinoma, 1; peripheral neuritis, 1; Landry's paralysis, 1; hemiatrophy of brain, 1; asphyxia neonatorum, 1.

Also experiments and studies were conducted on animals to determine in some degree: 1, the normal structure of ganglion cells; 2, the effects of post-mortem processes, 3, the effects of artificial heating, 4, the effects of acute alcoholic poisoning; 5, the effects of snake poison, 6, the effects of cold and starvation.

The conclusions which it is believed may be justified by the study of this material it is intended here briefly to summarize:

I. Technics. Of the fixing-agents recommended for the preservation of the chromatic structure of ganglion cells, the writer has used extensively Lang's fluid, alcohol of ninety-five per cent., and Van Gehuchten's fluid. Formalin in concentrations varying from five to twenty per cent.; formalin in five-per-cent. solution, saturated with bichloride; saturated solutions of picric acid and bichloride; and saturated aqueous solution of bichloride—have all been tested with fairly satisfactory results, but without finding in them any distinct advantage over other fluids. Lang's solution has proved generally unsatisfactory and was discarded entirely. Under its action the chromatic structures appear roughly granular and in thin sections often indistinct in outline. The uneven penetration of the acetic acid and metallic salt leaves many confusing appearances, especially in deep-lying nuclei, and the sections of tissues hardened in this fluid fade more rapidly than with other methods. In uniformity of results probably nothing is superior to alcohol, ninety-five per cent. or absolute, as originally recommended by Nissl. Van Gehuchten's fluid has proved very reliable in the writer's hands, and may be highly recommended, especially on account of its rapid penetration.

Among many proposed modifications of Nissl's staining-method, the writer has found none superior, except for special purposes, to the following very simple procedure: Stain the section for one or two minutes in a one-per-cent. aqueous solution of methylene blue, heating gently. Wash in water; decolorize in absolute alcohol until the alcohol no longer visibly dissolves the stain. Clear in oil of cajuput and mount in Canada balsam. Neither in the addition of alkalies to the dye nor in that of aniline oil to the alcohol have distinct advantages been noted.

For differential staining of the "achromatic" reticulum, Held's method with erythrosin and methylene blue has been used with satisfactory results. The most perfect demonstration of the cyto-reticulum secured by the writer has been in freshly teased specimens fixed by heat, 100° C., and stained either by methylene blue alone or by erythrosin and methylene blue; but this procedure is not to be recommended for general purposes.

It may seem almost a superfluous statement, but it is nevertheless a conclusion that has been reached only after long study and consideration, that when fresh nervous tissues, cut in pieces not more than two or three millimetres in thickness, are treated with alcohol, ninety-five per cent., or by Van Gehuchten's fluid until thoroughly penetrated, full reliance may be placed upon the appearances that the ganglion cells may present, and any serious disturbing effect of fixation and staining may be thrown out of account.

II. Histology.—The present study has not been directed toward the investigation of many of the finer details of cellular structure, but has had reference mainly to the chromatic elements specially demonstrated by methylene blue. From the minute study of normal and pathological specimens, aided materially by the use of artificial light, apochromatic lenses, and an achromatic condenser (on which oil should be placed), the writer concludes that the so-called chromatic substance of the human ganglion cell is invariably arranged in the form of a network, with nodal thickenings very prominent in the anterior horn cells, Purkinje's cells, and the cells of the spinal ganglia. In Purkinje's cells, however, the chromatic threads connecting the chromophilic bodies are much thicker than in the cells of the spinal cord and ganglia.

On comparing sections stained by Held's method (erythrosin-methylene blue) with those stained by methylene blue alone, and by attending to the above details of microscopical technics, the writer finds that the so-called "achromatic" reticulum of Held is always demonstrable by methylene blue and is not strictly oxyphile, although much more so than are the nodal thickenings, *i.e.*, the chromophilic bodies. It does not appear, therefore, that the use of erythrosin, in so far as it demonstrates this reticulum, is of any great advantage over the ordinary method of staining by methylene blue. Moreover, under the above conditions there appears to be no great difficulty in discerning the fibrillar structures of cell processes as described by Flemming, this character being very distinct in the dendrites of Purkinje's cells; although the writer finds that these fibrils possess numerous lateral anastomoses, as shown in Held's drawings of cells and processes stained by erythrosin.

In addition to this cyto-reticulum, chromatic or achromatic, stainable by both methylene blue and erythrosin, there is a cytoplasm not fully demonstrable by either dye, but with acidophile tendencies, in which it is believed that there are important pathological changes, the early evidences of which are beyond the reach of any method of demonstration yet described.

Of the radiating rows of oxyphile granules depicted by Held at the roots of axis-cylinder processes, the writer has been able to find only indistinct traces. In the thinnest and most intensely stained specimens that could be secured this area appears granular, but the granules are usually distributed irregularly.

The coarsely reticular portion of the cell body is surrounded partly by a finely granular oxyphile cytoplasm similar to that found in the axis-cylinder process, and corresponding to Held's "axis-cylinder Geflechte."

A very abrupt and distinct line of demarcation between this oxyphile envelope and the coarsely reticular portion of the cell body may be demonstrated, in freshly teased specimens, in what may be termed the polar dendrite. Probably the continuation of the granular oxyphile substance, *i.e.*, of the axis-cylinder process, fills in the meshes of the reticulum of the cell body. If this be true, the oxyphile cytoplasm furnishes the material which undergoes pigmented and

other forms of degeneration, a great variety of stages of which were noted in the present cases. If this be true, also it follows that the essential lesions that lead to the loss of function and conducting-power of the nerve cell are to be found, not in the chromatic reticulum or bodies nor in the so-called achromatic reticulum, but in the inclosed cytoplasm. Moreover, this granular oxyphile substance of the axis-cylinder process is found abundantly enveloping the dendrites, at least of motor ganglionic cells; and this fact must be regarded as evidence that the dendrites as well as the axis-cylinder process take part in the function of conducting impulses.

This conclusion has been already reached by Held and Apathy, working with entirely different technical methods.

III. Post-Mortem Changes in Ganglion Cells.—The examination of the first few cases of the present series emphasized the necessity of determining the effects of cadaveric processes in the chromatic structures of the nerve cell. Observations were therefore made upon the course of putrefactive changes in the ganglion cells of animals, whose brains and cords were exposed to the air for periods varying from one to seventy-two hours, at different seasons of the year. Comparisons were then made with material secured from autopsies. From these observations it appears that the earliest cadaveric changes consist usually in:

1. Nuclear changes. The chromatin of the nucleolus diffuses through the nucleus, causing broad thickenings in the intranuclear network or in the nuclear membrane, and leading finally to a deep and diffuse chromophilia of the nucleus. The nucleolus may become subdivided. In advanced stages the nucleolus shrinks, becomes very small, and the outlines of the darkened nucleus are shrivelled and irregular.

2. Changes in the chromatic reticulum of the cell body. These consist essentially in a granular subdivision of the chromophilic bodies and reticulum, without actual loss of chromatic substance. This alteration gives a characteristic uniformly granular appearance to the cell body, which is not difficult to distinguish from any vital pathological alteration as yet encountered by the writer. Vacuolation is a nearly constant and sometimes very prominent feature of the process. Similar changes, accompanied by rupture and shrinkage, early affect the dendrites. No uniform sequence or rate can be given for the progress of cadaveric changes, which follow the ordinary rules of putrefactive processes, being influenced by the condition of the tissues at death, by the character of ante-mortem and post-mortem infections, and by many local external conditions.

IV. Changes in Ganglion Cells in General Diseases.—(*a*) Infectious diseases. In all of the specific infectious diseases coming under observation, cellular lesions of varying extent were found in the central nervous system, but the prominent feature in this group of cases was the lack of uniformity in distribution and intensity of these lesions. The changes embraced nearly every variety of acute cellular alteration that the writer has found described, including central or peripheral, partial, circumscribed, or complete chromatolysis, eccentricity of nuclei and nucleoli, and apparent loss of processes. In some regions the changes seemed to affect the chromatic substance only, while the nucleus and cyto-reticulum appeared intact; in other instances, to the simple chromatolysis was added a variety of changes in the cyto-reticulum, cytoplasm, and nucleus.

In pneumonia the medullary nuclei suffered most severely, while the cortical cells and lower spinal stichochromes often appeared little affected.

In typhoid fever the lesions were usually more general, and in the cortex were much more marked.

In the case of tetanus the cortical cells suffered most, and in this region the stichochromes were uniformly and markedly bleached. There were moderate changes in the deep medullary nuclei, very few in the twelfth nucleus and in the cord.

In meningitis, empyema, peritonitis, septicæmia, pyæmia, and pernicious malaria, lesions of very irregular distribution were observed.

In most of the seventeen cases of this group attention was continually drawn to the presence of perfectly normal-looking cells, usually stichochromes, either lying singly in nuclei of which the other cells were much damaged or over larger areas which appeared to be unaffected by the fatal bacterial toxæmia. The irregularity in the occurrence of the lesions is well illustrated in a case of meningitis, in which cells of the twelfth nucleus immediately adjacent to a tuberculous exudate showed only slight chromatolysis, while the more distant deep-lying nuclei of the same section were entirely bleached.

(*b*) Auto-intoxications. Under this heading are grouped twenty-one cases, including uræmia, eclampsia, sunstroke, diabetic coma, epilepsy (fatal from other causes), secondary pernicious anæmia, and leukæmia. In all of these cases cellular lesions were found, of the same general character, and, with some exceptions, with the same lack of uniformity in distribution and intensity as in the preceding group.

From the study of seven cases of uræmia the writer has been unable to find any characteristic lesion of the nerve cells in this condition, all the changes observed having been noted in a great variety of entirely different diseases.

In one of three cases of eclampsia, fatal in the twenty-first successive convulsion, the nuclei of Purkinje's cells were markedly shrunken and chromophilic and the nucleoli enormously swollen. The other cases had few convulsions and did not show this peculiarity. Its significance is of course uncertain.

In one case of sunstroke there was marked bleaching of most cortical and medullary cells. In another —temperature, 109° F.—very slight changes of the same character (uniform chromatolysis) were observed in the medullary nuclei only.

The stages of chromatolysis exhibited by the ganglion cells in sunstroke appear to be identical with those induced in rabbits by artificial elevation of temperature.

(*c*) Acute poisoning. In cases of acute alcoholism rather rapidly fatal from the effects of the drug alone, the usual lesions, now frequently described, were observed. The characteristic bleaching of the cells was here of somewhat uniform distribution, but not invariably so in every case.

In two cases of carbolic-acid poisoning, fatal within two or three hours, no characteristic lesions could be found. Possibly cases of longer duration might show a characteristic lesion referable to this common poison.

In acute morphine poisoning, somewhat peculiar changes were noted throughout the cortex and medulla. These consisted in the appearance of irregular areas in the bodies of the cortical and medullary stichochromes, affected by a peculiar form of chromatolysis; in great irregularity of outline of the cell body; and in the heaping of masses and rods of chromatic substance about one edge of an eccentric nucleus.

In a case of hydrochloric-acid poisoning, although the effects of the acid were distinctly noticeable in the blood of the general circulation, no peculiar changes were found in the morphology or staining-reaction of the nerve cells.

(*d*) Non-toxic conditions; mechanical disturbance of the cerebral circulation. In a group of cases characterized by mechanical obstruction to the cerebral

circulation, very uniform and profound cellular changes were found throughout the brain and medulla.

These cases include three of hemorrhagic pachymeningitis, three of subdural hemorrhage, and one each of intraventricular hemorrhage, thrombosis of the basilar artery, and acute ependymitis.

In these cases all the more advanced stages of diffuse chromatolysis, up to almost complete disappearance of chromatic substance, were found. Here the chromophilic bodies were not subdivided, but appeared to shrink gradually, leaving finally only the original and now very faint cyto-reticulum. The uniformity of distribution of this chromatolytic process was a very striking feature in these cases, very few cells escaping extreme alterations, limited usually to the chromatic structures. In all of the cases there was distinct microscopical evidence of venous stasis in the circulation, and to this factor, arterial anæmia and venous congestion, the writer must refer the chromatolytic changes. The cellular lesions found in this group of cases appear to resemble closely the effects induced in the lumbar cord by ligature of the abdominal aorta.

V. General Considerations.—From these observations on the condition of the ganglion cells in various infectious diseases, it appears that very virulent toxæmias may and frequently do fail to cause any alteration in nerve cells demonstrable by Nissl's method. In fact, it would seem that the chromatic reticulum and bodies, especially of the stichochrome cells, are structures which are comparatively resistant to the action of many bacterial toxins. The most perfect examples of the motor ganglion cells of the cortex secured in the entire course of this study came from a case of intra-alveolar pneumonia, of septic character from the first and terminating in prolonged delirium and coma.

In a case of rapid septicæmia experimentally induced in a rabbit, many spinal stichochromes were found harboring bacilli in the bodies of the cells, which nevertheless showed slight or no evidence of chromatolysis. Babes has observed the same condition in the spinal ganglia in leprosy. In nearly all the bacterial toxæmias examined, the twelfth cranial nucleus was found comparatively little affected or quite intact

Further, the conclusion seems justified that the lesions actually found in the brain and medulla in these cases are not wholly referable to the direct action of the circulating toxin, but to some other intermediate agency. Otherwise, it becomes difficult to explain the very frequent occurrence of one medullary nucleus practically intact, immediately adjoining a second of which the majority of cells are in an advanced state of chromatolysis; and even more difficult to explain the presence of nearly or quite normal cells in the midst of badly altered ones.

From the marked resemblance of the cellular changes in these cases to those known to follow the destruction of axis-cylinder processes after experimental section of nerve trunks, or the anæmia caused by ligation of vessels, there is strong evidence for believing that most of the alterations of nerve cells seen in the above infectious diseases are not due to the direct action upon the cells of the circulating toxin, but follow after loss of function in cell processes or loss of blood supply in capillary foci. Such intermediate lesions may reasonably be referred to disturbances of local circulation, œdema of tissues and meninges, capillary embolism, thrombosis, and stasis, obstruction in pericellular lymph spaces, and lesions of nerve trunks. Another possible intermediate factor in these cellular changes must not be ignored. In some of the cases of uræmia of the present series, the medullary nuclei, especially the tenth nucleus and the "nucleus ambiguus," suffered very much more than in others, and in these cases the clinical record showed that the patient had exhibited extreme dyspnœa and cardiac weakness for some time before death, while in other cases death occurred suddenly in convulsions. Also in cases of pneumonia the above medullary nuclei were always badly damaged. These and a number of related observations seem to point to the probable importance of overaction and fatigue in determining the distribution of these cellular lesions in infectious diseases.

In another group of infectious diseases in which the virus is located principally in the central nervous system, *e.g.*, hydrophobia, and of which the present study includes but few examples, it is evident that the presence of toxins and bacteria in and about the nerve cells leads to extreme and widespread cellular lesions affecting the cyto-reticulum, cytoplasm, and nucleus, as well as the chromatic bodies.

From the study of the cases of poisoning by chemical agents, it appears that these poisons may in rapid cases abolish nervous function without leaving demonstrable lesions in the nerve cells. On the other hand, when the action of the poison is more prolonged, at least twelve hours, these cases seem to present very marked and often characteristic changes in the chromophilic substance. Similar conclusions have, of course, long ago been drawn from the experimental study of the effects of various poisons on animals, and the present cases, while furnishing examples of the effects of two more of these poisons, merely indicate how far the results of experimental study may be applied to the ordinary cases occurring in the human subject. How far the influence of the above-mentioned intermediate conditions—disorders of circulation and loss of function in cell processes—may be traced in this class of lesions, is a subject deserving consideration. Dilatation of capillaries is a marked feature in the alcoholic brain, and the lesions are identical in appearance with those of artificial anæmia; while morphine has a specific action on nerve fibres, and eccentricity of nuclei is strikingly frequent in fatal poisoning by this drug.

General Character of the Lesions Observed in Ganglion Cells in General Diseases.—The minute examination of the structure of the altered cells throughout the present study indicates that in most acute lesions the process of chromatolysis is one and the same, although different stages may present very dissimilar appearances. In the lesions referable to local anæmia and consisting in uniform fading of the chromatic substance, the chromophilic bodies appear to shrink gradually, leaving the chromatic or achromatic reticulum faintly visible, but of uniform density throughout the cell body. Often the last remnants of the chromatic nodal thickenings appear as fine granules, which are integral parts of this reticulum. In this case the cell may have a faintly granular appearance. The stages of the process may readily be followed in the cases of mechanical obstruction to the cerebral circulation. Or the fading may begin at several points in the chromatic body, giving the cell a distinctly granular appearance at an early stage of the process, but ending in the same condition of complete loss of nodal thickenings and more or less uniform preservation of underlying reticulum. These changes may be noted after section of peripheral filaments or after the action of various poisons.

Besides the changes in the chromatic substance only, more significant lesions, affecting the nucleus, cyto-reticulum, and cytoplasm, may in some instances be found, and these alone seem to deserve classification as true degenerative changes. The nucleolus may be faded, swollen, vacuolated, subdivided, or displaced. The nuclear membrane and intranuclear network may be found granular, disintegrated, irregular,

or entirely absent. The cyto-reticulum may be uneven, granular, distorted by vacuoles, or may be invisible. The cytoplasm becomes the seat of vacuoles, it may become coarsely granular, and these granules may show altered staining-reactions and refrangibility. The cell borders and processes may become shrunken and irregular.

The writer finds, however, upon the closest possible scrutiny, no distinct difference in the appearance of the majority of cells in cases fatal from alcoholism, sunstroke, tetanus, and thrombosis of the basilar artery, or other mechanical lesions. All exhibit phases, often identical, of simple chromatolysis. Moreover, this uniform end result of the chromatolytic process may be reached without distinct change in the normal morphology of the nucleus.

These facts seem to indicate, further, that the cell which is thus by a variety of influences robbed of its chromatic substance must not be regarded as in a state of degeneration comparable to the condition of the renal cell suffering from the effects of arsenic, and no longer showing chromatic reticulum or stainable nucleus.

The true degenerative process may not and frequently does not begin, as the writer believes, until after chromatolysis is complete. In support of this conclusion may be cited, 1st, the common absence of nuclear changes in these altered cells; 2d, the preservation of their cyto-reticulum; 3d, the functional activity demonstrable in such cells in overheated rabbits; 4th, certain general considerations on the significance of the chromophilic substance of ganglion cells, presently to be noted.

The first two of these points have already been referred to. In respect to the third item, it may be said briefly that the writer has many times repeated the experiments of Goldscheider and Flatau in subjecting rabbits to high temperatures, and finds that the chromophilic bodies of the anterior horn cells may be largely obliterated, and yet these animals be running actively about the laboratory. However, the writer found it very difficult to avoid the fatal limit in the exposure of the animals to artificial heat, and does not fully agree with Goldscheider and Flatau in their claim that the motor functions of these extensively altered cells are practically normal, as in his experiments there were considerable motor paresis and extreme reflex hyperæsthesia, the animals sometimes dying unexpectedly in general convulsions.

The fourth point leads to the conclusions as to the significance of the chromatic substance of nerve cells:

1. Reference must again be made to the fact, amply demonstrated by the present study, that the chromatic substance of the nerve cell is much more susceptible to the influence of disordered circulation than to the action of very virulent bacterial toxins.

2. It is an extremely significant observation of Levi's, if it can be verified, that in animals the chromophilic bodies disappear during hibernation. The validity of this statement the writer is now investigating.

3. While the studies of Hodge, Mann, and Lugaro, on the effects of exhaustion on the nerve cell, have not shown that the exercise of functional activity leads to any reduction in the quantity of chromatic substance in the cell, these studies are now generally regarded as irrelevant to their subject, as the method of excitation employed—electrical stimulus—secures in no respect the condition of complete fatigue. The relation of the chromatic substance to the activities of the cell still remains, therefore, a matter of conjecture.

4. In the premature and even in the full-term infant, the chromophilic bodies have been found to be faint and imperfectly developed.

From these general considerations on the present state of our knowledge, the conclusion seems justified that the chromophilic substance of the ganglion cell represents a state of physiological nutrition, which may vary between the full development of chromatic bodies in the anterior horn of the lumbar cord in the human adult, and their temporary but complete absence in the motor cells of the hibernating animal.

Finally, while the chromatic substance of the nerve cell may be greatly diminished without the cell being necessarily in a state of pathological degeneration, it seems equally certain that when acute degeneration, in a strict sense, affects the ganglion cell, the process is usually evidenced by various forms of chromatolysis.

It would seem that we are still far from a systematized knowledge of the real pathology of the ganglion cell. No one who has not scrutinized most minutely and under most favorable conditions the structure of nerve cells can realize the difficulty of detecting changes in the reticulum and intermediate substance of these cells. Yet it is the impression gained from this study that until it becomes possible to demonstrate delicate morphological or chemical changes in the intermediate acidophile substance, the key to this branch of pathology will not be grasped.

SOME STATISTICS REGARDING THE CRIMINAL INSANE.

By EDWARD H. WILLIAMS, M.D.,

MANHATTAN STATE HOSPITAL, NEW YORK.

At the present time when there is so much agitation of the question of making more efficient laws governing expert testimony in cases of alleged insanity in criminals, it is of more than passing interest to review the criminal records of New York State prisons and insane asylums, and see what inference may be drawn from them as to the actual mental condition of all classes of murderers who have been apprehended during the past quarter of a century. There is little use of attempting to gather accurate statistics previous to about 1874, for the records kept were meagre and inaccurate; but since that time the number and exactness of the records warrant the supposition that they will afford some valuable and useful data.

During the past twenty-five years four hundred and fifty-nine murderers have been apprehended in the State. Of that number forty per cent. have been confined in insane asylums since their crimes were committed, and fully thirty per cent. were insane at the time of their crimes. These figures are deduced from a careful perusal of the records of the prisons of the State, in comparison with the reports and records of the State insane asylums, and the Matteawan State Hospital for insane criminals. But what is more to the point, these records show that fully twenty per cent. of all the murderers apprehended should, long before their crimes were committed, have been confined where they could not harm other people, their mental aberrations having been so pronounced, of such a character, and of such long standing that there was no reasonable excuse for their being allowed at large.

The following case which happened a few months ago illustrates this: A young man who lived in New York City, and who had always been a quiet and inoffensive boy, gradually became so erratic, eccentric, and obviously unbalanced mentally that his family became alarmed at some of his actions, which were sometimes very threatening. They accordingly called in a competent physician to examine him. The physician, after carefully studying his condition, pronounced him insane and advised his immediate removal to some institution for the treatment of mental disorders, as he considered him a dangerous man to be at large. This

did not satisfy his relatives, who accordingly called in another medical man; but he also made the same diagnosis and advised immediate confinement of the patient.

His friends, however, concluded that the very best form of treatment would be to have him fall in love with some suitable young lady. Accordingly they laid all manner of plans to have him thrown much of the time into the company of an amiable and unsuspecting girl. Things were getting on nicely with the young people until one evening, when without cause or warning, he drew a revolver and shot his sweetheart.

This is a case in which there is little doubt that a murder should have been prevented; but the records show that this is only one case in many. After the Matteawan State Hospital records have been gone over carefully it is found that fully twenty per cent. of all the murderers apprehended were just as obviously insane as was this young man, and they had been known to be so by fully as many people and for as long a time.

This being the case, either our laws are defective or are not properly observed. And in this connection Dr. H. E. Allison, superintendent of the Matteawan Hospital, has recently published some statistics which explain why the plea of insanity is not more frequently resorted to by lawyers, even when there is evidence that their client is insane. Dr. Allison has gone carefully over all the New York prison records, and he finds that the average length of term of confinement of prisoners (including those with life sentences) is only a trifle over two years.

On the other hand, the average length of term of confinement in the asylum for insane criminals is over four years—practically twice that of prison life. The aim of the lawyer, of course, is to get for his client the shortest sentence possible, in case he is convicted; and, knowing that if he is declared insane he will be sent to the criminal asylum, where he stands a good chance of remaining twice as long as he would in prison, the lawyer is accordingly chary of advancing the plea of insanity.

The prevalent idea is that feigned insanity is a common "dodge," frequently resorted to and often successful; but as a matter of fact there are on record only two such cases during the last decade in New York State. In both these cases public sympathy was so strongly with the accused that one plea would have answered about as well as another; for acquittal was practically assured regardless of the line of defence.

On the other hand, insane people are constantly being condemned to death or penal servitude, regardless of their mental conditions. The Lizzie Halliday case is one of the most striking of modern times. She remained in prison only twenty-one days after being condemned as a common felon, her mental aberration being so obvious to the prison authorities that she was removed to the hospital for insane criminals. Her conviction was the more deplorable, as well as inexcusable, from the fact that her crime was practically motiveless, and because she had been released from an insane asylum only a few months previous to her crime.

The general public should learn that mental diseases are difficult to detect, and that the opinion of the average citizen, lawyer, judge, or physician is of little value as compared with that of an experienced alienist. Until this fact is generally recognized by the men in the jury box, justice is sure to miscarry in a large percentage of cases.

It is reported that the health-board bill has been killed in committee and that the dispensary bill has suffered the same fate. So much for the physicians not standing together and being consistent in their demands.

Progress of Medical Science.

The Surgery of the Stomach.—At a meeting of the French Academy of Medicine, held on February 8th, M. Doyen gave his experience with regard to the result of one hundred and forty-six cases of surgical operations upon the stomach. Of these, sixty-six were malignant, and eighty non-malignant. There were twenty-two deaths in all, and twenty of these were in cases of cancer. Of his last fifty-five cases, fifty were successful, five of the patients being *in extremis* when they came under treatment. Gastro-enterostomy is a proper treatment for dilatation and ulcer with or without hæmatemesis. Roux's method is the only satisfactory one; it avoids all danger of infecting the peritoneum. M. Doyen makes use of the lever compression forceps, which were originally made for compressing the pedicle of ovarian tumors. Recovery is undoubted in cases of serious dyspepsia or when there is ulceration without pyloric stenosis. The patients eat like everybody else, and are quite unaware they have a stomach. The operation is also of great use in patients who apparently suffer from intestinal dyspepsia; hæmatemesis ceases after its performance and the biliary function is re-established.

The Use of Anæsthetics.—*The Lancet*, referring to a fatality which occurred in the Woman's Hospital in Euston Road, in the case of a woman who was being operated on for cancer and to whom nitrous oxide followed by ether was administered, remarks: "We have not received any particulars as to the means adopted to restore the woman or whether the hemorrhage was severe. In all such cases positive warmth and guarding the patient from the effects of hemorrhage are undoubtedly the most important points for attention both before and during the operation. The fact is established that both chloroform and ether cause a fall of body temperature and so increase shock unless the trunk and limbs are kept wrapped in flannel or cotton wool. The fall of temperature under severe abdominal and vaginal operations, again, is considerable. A profound anæsthesia allows a considerable drop in arterial tension, which has been shown to be least when the limbs and pelvis are placed at a higher level than is the head. Again, saline transfusion of Ringer's fluid certainly lessens the collapse in such cases when the bleeding, always severe, is excessive." A death under chloroform occurred at Kidderminster Hospital, in which case the house surgeon administered the anæsthetic in the Scotch fashion, without apparatus. *The Lancet*, commenting on this accident, says: "We so often hear that the Scotch schools never meet with casualties under anæsthetics, because they always use chloroform and prefer to dispense with any apparatus. A glance over the long list of casualties under chloroform will unfortunately show that whatever charm Syme exercised during his life has not survived to his followers, and overdosage with chloroform proves as fatal to those who hail from beyond the Tweed as well as 'down south.'"

Cocaine Poisoning and its Prevention.—A. Pozzi, in his article, "Ueber die Aetiologie und Therapie des unstillbaren Erbrechens der Schwangeren" (*Therapeutische Wochenschrift*, No. 37, 1897), in referring to Dr. Tibone's treatment, gives some valuable data concerning cocaine. He says that idiosyncrasy and intolerance are manifested more often for cocaine than for any other anæsthetic, and that from therapeutic doses unpleasant symptoms frequently arise, due to the general and not to the local action of the drug. Numerous deaths have been reported from doses varying from 0.15 to 0.05 cgm. Cocaine should be employed with

great care, beginning with small doses, so as to ascertain the susceptibility and tolerance of the individual. The poisoning-symptoms develop at any time from one to ten hours, show various degrees of intensity, are paralytic or spastic in nature, and are associated with dizziness, nausea, vomiting, and great irregularity and frequency of pulse. Since heart paralysis takes place subsequent to respiratory paralysis, according to Battistini, in the spastic form chloroform should be administered. For psychical excitement, chloral is indicated; for respiratory paralysis, artificial respiration; in all cases of poisoning, elevated position and inhalation of amyl nitrite. For syncope, give excitants. To neutralize the vasoconstrictor action of cocaine, Gauthier recommends the addition of nitroglycerin in the following formula:

R Cocaine hydrochlor.	0.2
Aq. dest.	1.0
Sol. nitroglyc. (one per cent.)	gtt. x.

M. S. For subcutaneous injection.

The absorptive power of the various tissues must also be taken into consideration; in subcutaneous tissue, especially that of the head, absorption takes place very rapidly. More important than the size of the dose is the degree of concentration, and, since the result from a weak solution is the same as from a strong one, the use of a one or a two per-cent. solution recommends itself. The total dose should not exceed 0.15 to 0.20 cgm. No injection should be made with the patient in the horizontal position, and veins should be avoided. Reclus, who recommends these precautions, has made thirty-five hundred injections without a single manifest untoward symptom. The cocaine solution should be fresh and pure According to Battistini, such a solution remains clear upon the addition of sulphuric acid; if coloration occurs, then ignin and ergonin are present.

Hæmatoporphyrinuria.—Schulte (*Deutsches Archiv fur klinische Medicin*, lviii., p. 314) reports two cases of the above—one following a prolonged use of sulfonal, the other depending upon lead poisoning. Worthy of mention is the fact that in the first case the urine was strongly acid, and remained so even after the administration of twenty-four grains of citrate of sodium. Further, hæmatoporphyrin disappeared when the administration of the drug was stopped, and did not return again when sulfonal was once more used.

On the Sputum of Pulmonary Carcinoma. — P. Hampeln (*Zeitschrift fur klinische Medicin*, xxxii., 3, 4) claims that carcinoma of the lungs is not very rare, nor is the diagnosis so very difficult. He admits, however, that the symptoms produced by isolated, oftentimes metastatic carcinomatous tumors are very obscure. On the other hand, diffuse carcinoma of the lung, generally primary, gives a fairly characteristic symptom complex: 1, symptoms of unilateral consolidation of lung tissue, causing either retraction or expansion of the thorax; 2, irritation of the bronchi, producing cough and expectoration; 3, irritation of the pleura, producing exudation of all kinds; 4, pressure on the neighboring organs, particularly on the nerves and veins; 5, increasing cachexia. Added to these symptoms is the character of the sputum. Macroscopically the bloody character of the sputum is to be observed; generally the hæmoptysis is very mild and recurs two or three times; more rarely the pulmonary hemorrhage lasts a long time, though at no time is the bleeding copious. The hemorrhagic character of the sputum, its tenacious consistence, its early occurrence—these facts are of great diagnostic importance. The discovery of carcinomatous tissue in the sputum is of course almost pathognomonic, though this is extremely rarely found. Microscopically the writer lays great stress upon the discovery of polygonal alveolar epithelium, often pigmented, which in isolated cases is found in the sputum of many diseases, very rarely in normal sputum. If, on repeated or even on comparatively few examinations, such polymorphous polygonal epithelial cells alone are found, or there are found in overwhelming numbers cells with sharp contour, containing nucleoli, the cells either occurring in masses or separated, the inference is that a pulmonary new growth is present; indeed, the writer claims that the above microscopical picture presents itself only in cases of malignant tumor of the lung. The above-described cells are easily differentiated from the pavement and cylindrical cells; besides, the latter contain no pigment.

The Clinical Value of the Widal Test for Enteric Fever.—Dr. W. Gilman Thompson (*British Medical Journal*, December 18, 1897) draws the following conclusions from a brief study of five hundred and three cases of all kinds in which the Widal test was applied: 1. While the test is positive in the large majority of cases of enteric fever, and negative in the greater number of other diseases, there is a margin of error of eleven or twelve per cent. on each side of what might be called the normal line, between cases in which the test fails when it ought to succeed, and succeeds when it ought to fail, in order to make it of real clinical value. 2. This total of twenty-three per cent. of possible error unfortunately includes just those cases in which there is the greater doubt upon the purely clinical side. 3. As a genuine diagnostic aid, the test has about the value of the diazo reaction in typhoid urine or the study of leucocytosis in pneumonia—that is, it is confirmatory in connection with appropriate symptoms, but misleading if positive reliance be placed upon it. 4. The fact that an expert bacteriologist is required to make the test is offset by the ease of transportation of specimens of dried blood, which long retain the power of reaction, and it is greatly to be hoped that further possible improvements in technique may place this most ingenious test upon a firmer practical basis than can at present be claimed for it.

Ophthalmic Crises in Tabes Dorsalis. — P. K. Pel (Amsterdam) reports a case of locomotor ataxia with paroxysmal disturbances of both eyes, which consisted of irritation of the sensory, secretory, motor, and vasomotor nerve fibres. The most prominent symptoms were severe burning, lancinating pains in both eyes and their immediate neighborhood. During as well as after the attack an hyperæsthesia of the eyes and their surroundings could be confirmed. The psychical condition of the patient also showed slight changes during the attacks. Pel designates these attacks as tabetic ciliary neuralgias with marked vasomotor and secretory symptoms, and looks upon them as true ophthalmic crises (crises ophthalmiques).—*Wiener klin. Rundschau*, January, 1898.

Treatment of Gonorrhea.—Dr. Jules Janet (*Revue de Thérapeutique*, December 15, 1897), in a lengthy article on this subject, takes up the various complications of this affection. He divides extra-urethral foci into three classes: 1, prostatic foci; 2, foci of the glands of the anterior urethra; 3, the congenital para-urethral crypts and canals of the fossa navicularis and meatus. In order to find the prostatic foci, the patient is directed to urinate in two glasses and still retain some urine in the bladder. This done, he expels as much urine as the anterior urethra can contain, and the prostate is massaged, one or more drops of an aqueous liquid, white or yellowish-white in color, may

then appear at the meatus. This should be received on a glass slide and examined; if leucocytes and gonococci are present, they confirm the existence of a gonorrhœal focus in the prostate; if only leucocytes are present, the physician should still suspect prostatic infection and treat the patient accordingly. In these cases massage of the prostate often enables one to detect small indurated nodules, especially along the superior and lateral borders of the gland, and sometimes in the mass of the tissue itself. Again, there may be no prostatic anomaly perceptible, but more or less purulent liquid can be extracted. If this massage shows no drop at the meatus, the patient is told to evacuate the remainder of the urine contained in the bladder. If this third glass is more cloudy than the second, an analysis should be made; the character of the prostatic secretion can be ascertained. Search is made for glandular foci of the anterior urethra in the same way, massaging the anterior urethra instead of the prostate. If, after micturition, a purulent drop is obtained, with or without gonococci, the physician may expect infection of the urethral glands. Quite frequently he can detect in these cases small indurated nodules along the urethral canal. Sometimes they offer resistance and do not disappear on pressure, but more often they appear to sink into the urethra. They sometimes form para-urethral abscesses, and if allowed to follow their natural evolution they open by small orifices either on the sides of the frenum or the inferior angle or on the lips of the meatus. Sometimes they open simultaneously into the urethra and on the exterior, thus forming a fistula. The congenital para-urethral crypts and canals are often found in the neighborhood of the meatus. They are especially frequent in hypospadias. They are formed either by a large lacuna situated at the superior angle of the meatus or by different canals situated along the sides. As many as eight have been found in the same subject. The treatment of prostatic foci consists simply of massage of the prostate before each permanganate irrigation. The treatment of foci of urethral glands opening into the urethra consists in massaging the anterior urethra before each irrigation. If a para-urethral abscess does not open into the urethra, it should be opened freely and the wall curetted. If the abscess communicates with the urethra, the same procedure should be adopted. The urethral orifice should be found, and a silk thread should be passed by way of the meatus and should be allowed to remain. This keeps the fistula open and permits the liquid used in irrigations to pass along the silk. The fistula easily closes of itself when the gonococci disappear. Several cauterizations with the galvano-cautery aid in closing the opening. As to the para-urethral crypts and canals, they should be incised from the side of the urethra, so as to make a large communication between their cavity and that of the urethra. For this purpose the author has had a small automatic instrument made. It is composed of a fine cannula sound, which is attached to the blade. The sound is introduced to the depth of the para-urethral canal. A button on the blade is pressed toward the urethral orifice; the blade is pushed the length of the sound, and it cuts from one end to the other the wall that separates the canal from the urethra. Irrigations soon complete the cure. The author finds his method of treatment satisfactory. In some cases the patient becomes accustomed to the permanganate, and it is advisable to use citrate of silver, 25 to 1,000, a few times and then to return to the permanganate. In the treatment of gonorrhœa complicated with stricture, if the stricture is sufficiently large (15 F. or more) not to provoke retention or to cause urethral obstruction under the congestive influence of irrigation, it should be left alone until the gonococci have disappeared, and then any necessary dilatation may be practised. If, on the other hand, the stricture is very narrow and if there is vesical retention, it would not be prudent to follow this method of treatment, as there would then be the risk of complete retention under the influence of irrigations. In such cases dilatations and irrigations could be practised simultaneously. The patient should evacuate the bladder, and a small irrigation of borated water should be made. The bladder should then be filled with the borated water. Next, dilatation should be practised, after which the patient should evacuate the borated water; and then should follow a complete irrigation with permanganate, 25 to 1,000, during the first séances. When a No. 18 sound can be passed, dilatation may cease and the irrigations may be completed, dilatation being resumed later. When cystitis complicates gonorrhœa it may be the result of irritation of the bladder by the soluble products coming from the posterior urethra, or it may come from an extension of the inflammation of the posterior urethra to the bladder wall, or it may perhaps be due to infection by a secondary microbe—the bacillus coli or other cocci. The gonococci are so rarely encountered in cystitis that one can say that practically they are not cultivated in the bladder. The large number of cases of gonorrhœic cystitis are due to irritation, as one can easily recognize by analyzing the second glass of urine. The treatment in such cases is the same as for ordinary gonorrhœa, care being taken to use weak solutions in the beginning and to introduce only small quantities of liquid successively into the bladder. Permanganate solutions cause the soluble products due to the urethral gonococci and the inflammation that they occasion to disappear. If, on the contrary, the cystitis is infectious—which fact will, on analysis of the urine, be recognized by the innumerable microbes, coli bacilli, or cocci—the treatment by permanganate will suffice to exterminate the urethral gonococci, but will have little action on the secondary microbes contained in the bladder. One should, nevertheless, resort to disinfection of the bladder by silver salts, but it is more simple to unite the two treatments by mixing in the same solution the desired quantity of each drug. If prepared immediately before being used, these substances do not act upon one another. The author generally uses twenty-five centigrams of permanganate to one thousand parts of water, and adds twenty-five centigrams of nitrate of silver or five centigrams of sublimate. If the secondary infection persists after the disappearance of the gonococci, one may use irrigations of nitrate of silver or of the citrate, which is not so painful as the former. In the treatment of gonorrhœa complicated with orchitis, the author has attempted the usual irrigations during the acute stage, but against his better judgment. Traumatisms caused by these irrigations exaggerate rather than allay the congestion of the epididymis. It is preferable in these cases to suspend treatment during the acute stage. The acute period passed, large irrigations of the permanganate soon effect a cure. In case of prostatitis the same procedure should be followed. In the presence of general complications of gonorrhœa, rheumatism, endocarditis, meningitis, and conjunctivitis, the urethral treatment should be pushed whether the urethritis or its complications are very acute or not. In a case in which the general complications are due to the toxins of the gonococci—and these cases are frequent—a cure of the general affection will be obtained by use of the irrigations: if, on the contrary, the case is due to a generalization of the gonorrhœal infection, the treatment will have no effect. It is necessary, however, always to practise the irrigations, in order to eliminate the primary foci of infection and the toxins which it produces, and to attack the extra-urethral focus if it is accessible.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 9, 1898.

NATIONAL QUARANTINE.

IT is reported from Washington that a strong opposition is being manifested against the passage of the Caffery bill, enlarging the powers of the Marine Hospital service, and it is thought the Spooner bill, which provides for a national commission of public health, to be constituted a bureau of the treasury department, will more probably be passed by Congress. We need not here discuss the relative merits of the rival bills, for we have already expressed our views and see no occasion to alter them. The one important thing, it is indeed an imperative necessity, is the immediate passage of some measure to protect the inhabitants, not only of the Southern States but of the whole Atlantic seaboard and indeed the entire country, against the pestilence which is more to be dreaded and more difficult to ward off than all the warships in the Spanish navy.

There is, however, one very strong argument in favor of the Caffery bill, or at least of intrusting national quarantine to the Marine Hospital service for this summer. Whatever the outcome of the present Cuban controversy, whether the coming summer see peace or war, the danger of importing yellow fever from the pesthole, which Spain's persistent disregard of the most elementary hygiene or even of simple cleanliness has permitted to exist, is most real. Only the greatest vigilance on the part of experienced guardians will offer the slightest guarantee against an epidemic invasion of our land. In the Marine Hospital service we have an organized body of educated physicians and experienced hygienists, who are stationed even now at most of the danger points and can be distributed to others without loss of time. On the other hand, if a new bureau is to be established, it is beyond reason to hope that the complicated machinery of such an organization can be gotten into smooth running-order within the few days of safety that remain. Indeed, April 1st, if we mistake not, is the date for the establishment of quarantine against yellow fever in the Southern ports. How would it be possible to gather together a corps of experts in epidemiology, of men who are familiar with yellow fever and are themselves protected against it, to assign them to their stations, to establish these stations and provide them with all the necessary apparatus, and to organize a central bureau at Washington, all to be effective not later, let us say, than May 1st?

It is no time to try experiments when such an emergency as this exists. Even admitting that the Marine Hospital service is not perfect, it is at least existent, and it should, in our opinion, be at once clothed with the necessary powers, if only for the present summer, to do whatever is necessary to protect our people from a pestilence more destructive and more pitiless than war.

ALMSHOUSES IN MASSACHUSETTS.

THE report of the board of lunacy and charity of Massachusetts lays bare a startling state of affairs, and one that it is difficult to credit in our advanced stage of civilization. Over two hundred towns and counties maintain almshouses, the best managed of which makes no provision for the separation of the sane from the insane. This is bad enough, but the report goes on to state that in some of the almshouses it was found that there was not only no provision for the separation of the sane from the insane, but the sexes even were not separated by day or night, and the children were allowed to mingle at will with the adults. In those almshouses where the pretence was made of separating the sexes, the pretence was so palpable as to render it immoral in itself. Various efforts have been made at different times to induce the legislature to introduce the necessary reforms, but, owing to the action of an interested opposition, have up to the present effected no satisfactory result. This report should open the eyes of the public to so scandalous a condition of things, and should tend to bring about the much-needed alterations in the rules now controlling these institutions. A State that has been one of the foremost in inaugurating reforms should surely relinquish the old-time method of classing pauperism and crime in the same category, and compelling those whose only sin is to be old or crippled to herd with the scum of the earth.

THE HABITUAL-DRUNKARD QUESTION.

THE excessive consumption of alcohol is a subject that is now greatly exercising the minds of temperate people in some of the European countries. It is felt that the time has come when steps should be taken to prevent as far as is possible the lamentable effects that the abuse of alcohol is exerting on the health of the inhabitants. It is asserted that in France in particular the drinking-habit is absolutely sapping the strength and vigor of the nation. The people of Great Britain have long had the somewhat invidious distinction of being more addicted to strong drink than those of any other country. From the latest statistics published on the matter, however, the fact is gathered that France now heads the list in regard to the consumption per capita of alcoholic beverages. The Germans have ever been and are still the largest beer drinkers. England comes next, and then this country and France.

As may be naturally conjectured, Germany, France, Italy, and Spain, the most important of the grape-growing lands, are the largest consumers of wine, while the United States and England are the smallest. Of all peoples the French, with the possible exception of the Danes, imbibe the largest quantity of spirits. It is satisfactory to note that here the consumption of both spirits and wine has shown an appreciable decrease. In his annual alcoholic budget to the *London Times*, Dr. Burns recently estimated the drink bill of the United Kingdom for the year 1897 in round numbers at $760,000,000, an increase over the preceding year of about $16,500,000. In face of this condition of things it has been decided to take vigorous measures to protect, at least to a certain extent, the habitual drunkard from himself. The inebriate-legislation committee of the British Medical Association has issued a circular strongly advocating certain reforms in the existing laws regulating the treatment of the drunkard. The points to which it is considered legislation should have particular regard are: (1) power to substitute curative and reformative treatment of criminal inebriate offenders for their existing ineffective imprisonment in jail; (2) power to seclude non-criminal habitual drunkards, with due regard to the "liberty of the subject," in special curative institutions; (3) curative seclusion at the public charge for poor habitual drunkards. A bill embodying these proposals has been introduced into the English house of commons, and was favorably received. It may be mentioned that at the back of this movement are the fifteen thousand medical men belonging to the British Medical Association. That habitual inebrity is a mental and physical disease is now generally conceded; in fact, those who have made a study of the subject confidently assert that such is the case. If this, then, be so, it appears irrational, in addition to being decidedly hard on the drunkard, that he should be punished for his misfortune. Though men are not to be made sober by act of Parliament, judicious laws may assist them to overcome their failing, and therefore it seems that the bill now before the British legislature is a step in the right direction. In France the necessity of checking the widespread inebriety is recognized by all those who have the welfare of their nation at heart. Dubisson says that, while the population of Normandy has during the present century decreased by one-third, the consumption of ardent spirits has increased enormously. The mean duration of life has been reduced by more than half. Insanity, formerly unknown, is now fearfully prevalent; crimes of violence are rife; and stillbirths, rickets, scrofula, and congenital syphilis increase year by year. The same tale is told by physicians in all parts of the country. *Public Health* says: "The information thus elicited points to a grave state of matters in France, but the efforts of the medical profession to arrive at the truth and enlighten public opinion are a hopeful augury of success in what Dr. Laborde calls 'the struggle against the true enemy.' Many remedies have been suggested as a means of bringing about a change for the better, the most sweeping of which is that the French government shall have the monopoly of the manufacture of stimulating beverages, so as to insure their purity. On the whole, notwithstanding the fact that France and England and one or two of the other European nations have retrograded, there has been a marked decline in the consumption of alcohol throughout the world. This has been especially the case in America, where the decrease since 1888 amounts to about thirty per cent. Without a doubt, the most important phase of the drinking-question, at any rate to the medical profession, is to discover the best method of treating the habitual drunkard.

DEPENDENT AND HOMELESS CHILDREN AND THE NEW YORK STATE PLACING-OUT BILL.

Opinions have considerably altered in regard to the desirability of orphan asylums and institutions as a means of saving homeless children. The great objection urged against them is the disadvantages of massing children together in large numbers under artificial conditions. The substitute for orphan asylums adopted in many States of this country is what is termed the placing-out system, that is, finding a dependent child a home in some respectable family. This system, when properly carried out, is without doubt in every respect a great improvement on the old one, but unfortunately in this and other States it has been so abused as almost to become a public scandal.

William Prior Letchworth, writing on the matter in the *Sanitarian* for January, says: "The subject of State supervision is of such importance that I think it should receive the attention of the legislature of every State, and a system should be provided regulating the manner in which homeless children shall be placed in families, and providing a method of supervision over them afterward which is not obtrusive or offensive to foster parents who have received children, as members of the family, but which is nevertheless adequate to afford ample protection to the child. The function of the orphan asylum is to prepare children whose habits, manners, speech, and morals need reforming, for the family home, with as little loss of time as possible, and to prevent the breaking up of families in bereavement or distress by caring for their children until they are in a position again to take charge of them." Different States have different methods for placing out children, but probably those in force in Michigan most nearly approach the standard of excellence advocated by Mr. Letchworth. These are in brief as follows: "For general distribution throughout the State, the board of control issues a pamphlet circular, explaining how children may be obtained from the State school, with instructions as to what is required of foster parents after they have taken children. The pamphlet contains a list with the post-office address of all the county agents. Persons selecting children, either by a visit to the school or by correspondence, are required to make an application in a prescribed printed form. This is sent by

the superintendent of the school to the county agent of the county in which the applicant resides, who visits the home of the applicant and reports upon its fitness and the truthfulness of the statement made in the application. If this report is satisfactory, the child is then delivered to the applicant upon sixty days' trial."

The placing-out bill for New York State should in its new form commend itself to all classes, and it is to be sincerely hoped that it may become law. The first bill drawn up by the State board of charities met with opposition on the part of many of the philanthropic and charitable organizations in the State, chiefly on the grounds that it delegated too great powers to the State board of charities. As a consequence of this opposition a conference between the various charitable organizations interested in the matter was held, and the present bill, in a completely new form, was drafted, and appears to be altogether satisfactory. In the first place the bill referred to defines the term "destitute child" as meaning an abandoned orphan, or a destitute minor under the age of sixteen, who is an inmate of a public or private charitable institution, or is maintained by or dependent upon public or organized charity. Placing out is defined as the placing of that child in a family other than that of a relative within the second degree, for the purpose of providing a home for such a child. No person can receive such a child, nor can a corporation other than a charitable or philanthropic one place out such a child after this act becomes law, unless a license shall have been given by the State board of charities. No child can be placed in a family outside the State by a local officer charged with the relief of the poor. To the State board of charities is given the power to issue licenses to persons or corporations whom they deem proper to take care of children—no license to be granted to any person until six months after the application has been made. Such license may be revoked by the board, subject to a right of appeal on the part of the licensee. The State board of charities in fact acts *in loco parentis* and appoints inspectors whose duty it is to visit those families or corporations holding licenses. Attention is also paid to the religion of the child, as in as many cases as possible the child is placed with persons holding the same religious views as did the child's parents.

Changes at Columbia.—At a meeting of the board of trustees of Columbia University on April 4th, the resignation of Dr. James W. McLane, professor of obstetrics, was presented, and, at his earnest request, was accepted. Dr. McLane was made emeritus professor of obstetrics, retaining his seat in the faculty of the College of Physicians and Surgeons and remaining dean of the college. The vacancy in the chair of obstetrics was filled by the appointment, with the title of lecturer in obstetrics, of Dr. Edwin B. Cragin, a graduate of the College of Physicians and Surgeons in 1886. Dr. Cragin will also have charge of the Sloane Maternity Hospital.

News of the Week.

The Library of the New York Academy of Medicine.—The library committee announces that the suggestion has been received from a number of sources that the academy library be kept open (for members only) on Sundays, from 10 A.M. to 5 P.M. To do this would involve additional labor and expense, besides necessitating a change of bylaw; and before action is taken in the matter it has been thought best to seek an expression of opinion from the members of the academy by inviting them to cast an informal ballot. If the replies received indicate that the change is desired by a considerable number of the members, the committee will then take the matter under advisement, and will probably propose that the opening take place. We presume that "Sunday opening" means also holiday opening, for it is on holidays especially that great inconvenience is experienced by many members who would gladly avail themselves then of the library facilities, if they could.

The Massachusetts Medical-Practice Bill is being violently opposed by the Christian scientists and other faddists, whom the *Boston Herald* characterizes as occupying quarters of the highest intelligence, and this comic daily adds: "There has seldom been more talent and character arrayed against a proposed measure of legislation at a committee hearing than appeared in this instance." Boston always was and is funny.

Death of Professor Stricker.—The cable reports the death of Prof. S. Stricker, professor of general and experimental pathology and therapeutics in the University of Vienna. He was born in 1834.

The Dispensary Evil in Constantinople is not yet very great, but it is growing. There are two dispensaries in that city, which treated 2,299 persons in 1896 and 6,062 in 1897.

The Woman's Medical College.—The new building of the Woman's Medical College of the New York Infirmary for Women and Children, the opening of which we noted in a recent issue, is of seven stories. In the basement are eight clinic rooms. The first floor contains reception rooms and offices. There is a well-equipped chemical laboratory on the floor above, and the histological and pathological libraries are on the third floor. The amphitheatre extends from the fourth to the fifth floor, and seats about one hundred and fifty students. The dissecting-rooms are on the sixth floor.

Hospitals Closing.—The Astoria Hospital was closed on the first of the month, the managers having failed to form a union with some other institution entitled to receive patients at the city's expense. The St. John's Hospital in Long Island City is also in difficulties on account of the loss of receipts derived from the local government. The institution is managed by the Sisters of St. Joseph, and was opened six years ago. Last year work was begun on a four-story

brick structure, which was to cost $100,000, but when the building was far advanced work had to be suspended because the building-fund was exhausted. The borough authorities have been appealed to, but they give very little encouragement that relief will be secured. The Flushing Hospital is in the same predicament.

The University of Freiburg announces that all students attending the lectures there will be insured against accidents within the precincts of the university, including those met with in the gymnasium and while duelling, or during excursions conducted by the professors. In case of death about $4,000 will be paid to their families.

The Roentgen Rays in Court.—A judge of the superior court of Connecticut recently refused to make a ruling in a damage suit to compel the application of the *x*-rays to test the question of injury to a bone. Expert testimony had been introduced to show the value of the rays in such cases.

The Worshipful Company of Skinners has voted £1,000, the cost of opening vacant wards and building new out-patient rooms, to the City Orthopædic Hospital, Hatton Garden.—*The Medical Press.*

More Army Surgeons.—A bill has been introduced into Congress increasing the number of medical officers in the army by fifteen additional assistant surgeons, and authorizing the surgeon-general of the army, in emergencies, to appoint, with the approval of the secretary of war, as many contract surgeons as may be necessary, at not exceeding $150 a month.

The British Pharmacopœia.—The last literary work which Sir Richard Quain performed was the revision of the proofs of the forthcoming British Pharmacopœia. He was chairman of the Pharmacopœia committee of the General Medical Council, and it was one of his duties to revise the proofs of each edition of the Pharmacopœia.

"The Medical Press," with its not unusual ignorance of things American, in a notice of Dr. Weir Mitchell's "Hugh Wynne," kills and buries the author beyond recall. "This stirring and exquisitely written historical romance," it remarks, "is from the pen of no less a person than the late Dr. Weir Mitchell. We learn for the first time that this author was an accomplished writer as well as a sagacious physician."

Artificial Impregnation.—The Catholic authorities at Rome have rendered a decision forbidding the practice of artificial impregnation, devised by Sims. The reasons for this prohibition are not stated in the decree.

Obituary Notes.—Dr. Oliver Albert Judson, of Philadelphia, died at his home in that city on March 30th. He was born in 1830, and was graduated from the Jefferson Medical College in 1851. He served as brigade surgeon throughout the civil war, and at its close resigned with the brevet rank of colonel of the United States volunteers.—Dr. George S. Little died in Brooklyn on March 30th, at the age of seventy-three years. He was a graduate of the University Medical College in the class of 1848, and had practised in Brooklyn for thirty-five years.

The Divine Healer on Top.—The Kansas State board of health recently applied to the attorney-general for a decision concerning the enforcing of the medical-practice law in that State. The legal luminary cogitated for a while, and then delivered the opinion that the magnetic healers and the hypnotists and all the other quacks except divine healers can be prosecuted, but adds that the divine healers claim their power to come from Jehovah and that, as he understands it, the rights and privileges of Jehovah can in no way be regulated or restricted by the statutes of Kansas.

Association of American Physicians.—The thirteenth annual meeting of this association will be held in Washington, on May 3, 4, and 5, 1898.

The Ohio State Medical Society will hold its annual meeting at Columbus on May 4, 5, and 6, 1898, under the presidency of Dr. William H. Humiston, of Cleveland. Addresses will be delivered by Drs. Senn, of Chicago, and Hare, of Philadelphia.

A New Hospital Ship.—The *Creole*, a large and handsome vessel sailing between New York and a Gulf port, has been selected by Surgeon-General Van Reypen, of the navy, for use as an ambulance ship, and has been taken in charge by the government and sent to Newport News, Va., to be fitted there for hospital purposes. Wards will be arranged and light ports cut, so that wounded sailors will have the most cheerful surroundings. The *Creole*, when converted, will hoist the flag of the Red Cross Society and proceed to Key West for service with Captain Sampson's fleet.

The New York Skin and Cancer Hospital.—At the recent opening of this institution, noticed in our issue of March 12th, Dr. L. Duncan Bulkley, the originator of the hospital and its present secretary, delivered an address devoted to the history of the undertaking. The first patient was admitted to the old building in Thirty-fourth Street on Feburary 26, 1883. During these fifteen years the hospital has received about $375,000, of which $75,000 came from the board of patients and sale of drugs in the dispensary. The land and building are now practically free from debt. Since the opening of the hospital 25,031 cases have been treated, 3,010 of which were in the cancer department. The greater number of the patients were out-patients, and the total number of visits was 118,154. The number of prescriptions filled by the hospital druggist was 132,263. In the wards of the hospital there had been 2,872 patients, and the total number of hospital days was 165,077, of which 117,658 were free. Thirty physicians have served on the house staff during the fifteen years. It is now proposed to have clinical lectures in the hospital, free to all physicians. Mr. J. Cleveland Cady, the president of the board of managers, was the architect of the new building on Second Avenue and Nineteenth Street.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 9, 1898.

T. MITCHELL PRUDDEN, M.D., PRESIDENT.

(Continued from page 491.)

A Preliminary Communication on Studies on Ganglion Cells.—DR. JAMES EWING read a paper with this title (see page 513).

DR. CHARLES L. DANA said that the paper just presented was a most valuable and original contribution to the pathology of the ganglion cells, and those who had worked in that line could appreciate the amount of labor involved in its preparation. He had himself worked in this field, though not so thoroughly. He had examined the different parts of the nervous system in twenty-five or thirty cases, mostly in patients dying of alcoholism, but he had not published his results in detail, for the reason that he had not been able to find in these different brains anything significant of the poison which caused death. After various trials with Nissl's stain and different fixing-fluids, he had come to the conclusion that the simplest method was the best, *i.e.*, putting pieces of fresh brain (invariably within twenty-four hours) into absolute or ninety-five-per-cent. alcohol, staining with methylene-blue solution, and decolorizing with absolute alcohol. No aniline oil was used. His conclusions were very similar to those reached by Dr. Ewing. He had not been troubled with vacuolation at all in estimating the significance of the pathological changes. It had seemed to him that the existence of vacuolation of the cell bodies to any great extent was an indication of bad technique or of post-mortem changes. One thing which had seemed to him to indicate extreme cell degeneration or marked toxæmia was vacuolation of the nucleolus. He observed that it was noted chiefly, but not wholly, in Dr. Ewing's cases of toxæmia. One pathological picture, seen in three different cases, was an enormous pigmentation, especially of the larger cells, accompanied by chromatolysis and other signs of acute degeneration. He had seen it in two cases in which the patient died with very high temperature—as in alcoholism terminating with grave delirium and hyperpyrexia. Dr. Ewing had given beautiful pictures of the individual cell changes themselves, and they did not seem indicative of any special disease. However, one did get different pictures of cortical sections of the brain in different diseases, not so much because of any specific cell change, but because of the general peculiarities of the picture. Thus, there was a very general atrophy of the cells in old age, and in cases of morphine poisoning in which the patient had been practically starved for a considerable time. It was possible that by studying the frequency of certain kinds of cytoplasmic and nuclear changes in connection with vascular and neuroglia changes in different diseases, we might be able to find pathological pictures significant of the different types. It was along these lines that future work must be done.

DR. IRA VAN GIESON laid stress on the necessity of studying the nerve cell in the living or fresh condition in order to gain any reliable conception of its cytologic structures and interpretations of functions of these structures, for the best-fixing reagents furnished only a deficient and distorted picture of the living cell.

This had been well exemplified in certain of his studies on fresh human material and in a study in conjunction with Mr. Rolfe Floyd, of the living neuron-cell body in the ganglionated chain of the cockroach—Blatta. In this latter instance the cell body of the neuron consisted of a cyto-recticulum with rather broad meshes and a fluid of moderately thick consistence.

The anterior-horn cells of the frog, when taken from the living animal, demonstrated the same structures. This fluid element of the neuron-cell body or cytolymph, however, was very radically changed in its structure when subjected to the ordinary technical procedures for cytological investigation in sections under the microscope. Alcohol sublimate, acid fixing-media, Van Gehuchten's fluid, and the great majority of fixatives converted this cytolymph into a precipitate or colloidal deposit, as Held's important researches had shown.

These studies, the speaker continued, on the artificial condition of the cytolymph in the neuron-cell body, when viewed under the microscope after preparation by the standard and most modern fixing-reagents, should be held in mind in investigation of the parenchyma cell of the body in general. Most probably in the kidney and gland cells in general, the cytoplasmic granules with all their differential staining-properties were, in the light of these studies on the cytology of the neuron, merely precipitated or coagulated particles of the nucleo-albumin of the cytoplasm, which in the living cell did not exist in this form but were in solution and in a fluid form.

Nevertheless, although in sections with the very best methods of cytological technique this cytolymph appeared in an artificial condition, with a given fixative this artificial condition was a uniform one and was the expression of a chemical reaction between the nucleo-albumins and the fixative, which was definite and constant.

Now, the artificial condition of the cytolymph of the neuron after the employment of a given fixative being an exact and uniform factor, it was, then, a reliable and exact standard of investigating pathological conditions of the neuron, and was not such a fallacy in these investigations as might seem at first glance. Pathological changes could, therefore, be studied in the neuron by observing alterations in this precipitated or coagulated condition of the cytolymph, which, although an artifact, might be made to appear as a constant standard of comparison. Yet of course, as the auditors well recognized, there might well enough be changes of a chemical nature in this neural cytolymph, which such a plan of morphological study would fail to place in evidence. The whole question brought out the dependence of pathological anatomy upon physiological chemistry for the ultimate solution of most of its problems, and the imperative necessity of exact and conjoint investigations of the morphologist and physiological chemist in the action of fixing reagents upon the various cytologic structures, in order that we might have some notion of what we were writing about in the enormous amount of work that was being done on the cell in its hardened and artificial condition.

As to the function of these two structures—the cyto-reticulum and cytoplasm in the neuron—the speaker, from studies of the comparative cytology of the nerve cell, of its histogenesis, and of a variety of pathological conditions, felt justified in maintaining that the cyto-reticulum subserved the dynamic functions of the neuron. By means of this structure dendritic retraction and expansion took place. This structure, too, was the medium of conduction and transmission of nervous impulses. The cytolymph, on the other hand, was the seat of energy of the neuron. This energy of the neuron was used by the functioning of the cyto-reticulum. A certain amount of this energy residing in the cytolymph was drawn off, for instance, in the cycles of physiological activity of the nervous system,

and was recovered by the elaboration of the crude food supply in the lymph surrounding the cell into higher and more complex compounds in the cytolymph. (The speaker illustrated these points by blackboard drawings.)

In considering the effects of toxic agents upon the nerve cells and in examining the effects of acute and general somatic disease upon the neuron, the speaker had been forced to accept the same conclusion as expressed by Dr. Ewing, viz., that the exceedingly irregular action of the toxic factors in effecting changes in the nerve cells could not very well be ascribed to the direct action of the toxins alone. There must be some other exceedingly important intermediary or secondary factor in producing these changes, such as vascular fluctuations or localized escapes of toxins from the vessels through lesions in the vascular endothelium.

In alluding to the form of degeneration with eccentricity of the nucleus and centralized pallor of the precipitated cytolymph granules, he said that he had studied this form of degeneration, particularly in peripheral neuritis, lead paralysis, and in cortical motor cells in general paralysis, and recognized with other observers that this form of degeneration was concomitant with lesion of the axone, and he had therefore designated this degeneration as the axonal or secondary form. But he was not prepared to accept the converse of this statement, namely, that, given the appearances of this form of degeneration in the neuron cell body, the conclusion was always to be accepted that the axone was damaged.

Dr. Van Gieson in conclusion regretted the limited time for discussion and appreciation of a paper which in his estimation was the most important which had yet been written in the new epoch of the pathology of the neuron, namely, its study in the light of modern cytology.

Dr. Ewing closed the discussion, referring to the lack of specific quality in most of the changes demonstrable in ganglion cells by Nissl's method, to the significance of changes in the achromatic substance, and to the importance of Held's demonstration of the semifluid character of the chromophilic substance, which, however, he thought did not invalidate the observations previously made upon the chromophilic bodies.

A Preliminary Communication on a Method of Determining the Reaction of Post-Mortem Material, and its Application to Nerve Tissue.—Dr. S. Bookman read a paper with this title. He said that Held had shown that in half an hour after death the reaction of the nervous tissues became acid, and that this probably accounted for the precipitation of the Nissl granules. This had suggested to him the present line of investigation. The method, in brief, consisted in making an emulsion of the tissue to be examined by triturating it in a mortar with purified sand. This emulsion was then subjected to titration with centinormal soda, to determine the degree of acidity.

In the first experiment a piece of brain which had been in ninety-five-per-cent. alcohol for twenty-four hours was titrated and showed an acidity of 3 c.c. per gram. Five days later another piece of the same brain showed an acidity of the gray matter of 5.3 c.c. per gram, and of the white matter of 6.8 c.c. As, however, the alcohol seemed to exert an influence which could not be compared with changes occurring in material not in a process of hardening, a second experiment was carried out on material not so treated, and the figures here were 5.1 c.c. per gram of white matter and 2.1 c.c. per gram of gray matter, showing that the alcohol retarded the beginning of decomposition.

In another brain, three hours after death, the gray matter showed 3.1 c.c. per gram, and the white matter 2.8 c.c. Eighteen hours later, the gray matter showed 4.8 c.c. per gram, and the white matter 5.9 c.c. Forty-eight hours after the last experiment the gray matter showed 6.9 c.c. per gram and the white matter 5.7 c.c. Twelve hours later the whole mass showed 4.5 c.c. per gram. Thirty hours later the gray matter showed 5.3 c.c. The cord showed the following: twenty-four hours after death, 6.8 c.c. per gram; four days after death, 4.7 c.c. per gram, the cord substance having already gone over into the stage of decomposition, which was verified by decreasing acidity. Twenty-eight hours later it showed 4.4 c.c. per gram.

The decrease in rapidity of the approach of reduction in acidity in the two cases was explained by the fact that the brain remained exposed at a temperature of 68° F., whereas the cord was kept at a temperature twenty degrees below the same.

Dr. Bookman said that he had not completed this line of research, but he thought it not impossible that he would find that each disease had a reaction peculiar to itself, and that it would explain more fully the formation of the Nissl bodies. Held had shown that by immersion in carbonate of lithium after fixation the granular areas were dissolved, while the ground matters remained intact.

Dr. Ira Van Gieson remarked that the subject was a very promising one for study, especially in connection with the various forms of toxæmia.

The society then went into executive session.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 28, 1898.

Arthur M. Jacobus, M.D., President.

Bullet Removed from a Cervical Vertebra; Detected by the X-Rays.—Dr. A. M. Phelps presented a young man who, a year ago last November, while handling a revolver of No. 38 calibre, had accidentally discharged its contents into his neck near the thyroid cartilage. The place of lodgement of the bullet could not be determined at the time. He soon developed more or less paralysis of the left arm and experienced great pain in the shoulder, which extended down the back of the neck, and the neck was rigid and drawn toward one side. Two surgeons had made unsuccessful attempts to locate the bullet by the *x*-rays before the case came to Dr. Phelps. After making several efforts with the aid of the *x*-rays and different *x*-ray machines, he finally succeeded in locating the bullet near the body of the third cervical vertebra. An incision was then made from the mastoid process of the occipital bone along the posterior border of the sterno-cleido-mastoid muscle nearly down to the clavicle. The sterno-mastoid muscle was pulled forward and the deeper muscles were drawn backward, thus exposing the transverse processes of the cervical vertebræ. The nerves were also retracted. When the body of the third cervical vertebra was cut down upon a small discoloration was noticed, and this led into an opening. By means of the Girdner telephonic probe the bullet was easily located. A large portion of the cervical portion was cut away and the bullet removed. It had entered the canal and pushed the meninges forward, and was making pressure on the spinal cord. It had also injured the root of the third cervical nerve. The patient's recovery was uneventful. Without the aid of the skiagraph it would have been impossible to find the bullet. Lodged as it was in the body of the vertebra and invading the spinal canal, the bullet, if not removed, might have resulted sooner or later in total paraplegia.

The Local Examination and Treatment of Diseases of the upper Rectum and Sigmoid Flexure.—Dr. James P. Tuttle read a paper with this title. It was founded in the results of observations made for some time past with the proctoscope and sigmoidoscope, better known as "Kelly's tubes." These were first presented to the profession in 1895. What might be seen through the instruments, he said, could be inferred from the statement that he had by actual measurement found that the instrument embraced a field of twenty-five or thirty inches. Adhesions interfered with the examination, and so might also volvulus or intussusception. It was a most valuable addition to the armamentarium of the clinical teacher.

Neoplasms.—These were of paramount importance from a diagnostic point of view. They were frequently mistaken for functional or inflammatory disorders, and treated as such until too late to be amenable to operative procedures. This was especially true of carcinoma. It was his firm conviction that the systematic use of the Kelly tubes in all cases of irritation of the rectum, sigmoid, and lower colon would reduce the mortality from carcinoma of these patients fully fifty per cent. The appearance presented by the carcinomatous growths was typical, and not easily confounded with other diseases when the diagnosis was made by actual inspection. This was in striking contrast with the results of diagnoses found on the rational symptoms alone.

Fibrous and Adenoid Polypi. While these were common in the lower rectum they were not frequently seen in the sigmoid or upper rectum. Papillomata were rarely found in the rectum, but might be found at any point from the anus up. They were much more difficult to remove than fibrous and adenoid polypi, on account of their broad attachment to the mucous membrane. They bled freely on handling, and when they were cut or twisted off dangerous hemorrhage was likely to follow. They might be very easily mistaken for epithelioma, but might be distinguished therefrom by the healthy condition of the mucous membrane at their base, the absence of infiltration and of constriction of the calibre of the bowel, and by the fact that they occurred nearly always as multiple growths with absolutely healthy areas of mucous membrane between them. Flat, broad-based adenoid growths were comparatively frequent in the lower rectum, but were rarely seen higher than three or four inches from the anus. Submucous growths and those attached to the outer wall of the gut could not, of course, be seen through the Kelly tube, but fortunately this was not a serious drawback in actual practice. Regarding the growths situated above the portion of the rectum covered by the peritoneum, the speaker said that he believed it to be more feasible to operate through an inguinal incision than through the sacral incision. The common diseases of this portion of the bowel were, 1, simple acute catarrh; 2, hypertrophic catarrh; and, 3, atrophic catarrh.

Simple Acute Catarrh.—This was identical in its onset and course with an acute coryza. The bowels were constipated, and a sensation of heat and burning in the pelvis supervened. A watery and mucous diarrhœa occurred in the course of a few days. Normal health was rapidly restored under proper management, unless ulceration had occurred. In the first stage of the disease the mucous membrane was swollen and hot. Through the Kelly tube it appeared of a bright and shiny red, uniformly distributed, and there was an absence of varicose veins. In the second stage there was abundance of mucus present, sometimes in the form of mucous shreds. Rectal irrigation was the rational treatment for this condition.

Atrophic Catarrh.—Chronic atrophic catarrh of the rectum, sigmoid, and colon was a very common disease, representing about twenty-five per cent. of the cases seen in Dr. Tuttle's clinic. In the majority of cases it did not extend above the middle of the sigmoid flexure. Small fissures were constantly present around the muco-cutaneous junction, and were quite characteristic. They did not cause much pain, but gave rise to very intractable pruritus. The mucous membrane appeared dry and of a dark red color, with fissures through it. There was very little tenacious mucus on the surface. Attached to the wall of the gut might be seen small masses of inspissated fecal matter. There was frequently an impaction of small fecal balls in the ampulla of the rectum. Procidentia of the upper portion of the gut into the lower was a frequent associated condition. Through the tube this prolapse resembled the normal cervix uteri. It accounted for the difficulty of introducing the bougie and for the frequent mistake of diagnosticating these cases as strictures of the rectum. The treatment consisted in keeping clean this portion of the intestinal canal by irrigations with boric acid solution. When there was atrophy present the peristaltic and glandular activity of the intestine should be stimulated. Injections of half an ounce of a five-per-cent. solution of argonin were often followed by the happiest results. The diet should be of such a nature as to require but little intestinal digestion.

Hypertrophic Catarrh.—Hypertrophic catarrh occurred with a general catarrhal condition of the whole system. The mucous membrane appeared moist and sodden, and was covered with more or less purulent secretion. There were always more or less fluid and fæcal matter in the rectum except just after stool. The condition usually extended above the portion within the reach of the tube. The sphincters were relaxed, and the tubes passed in very easily. There were rarely any hemorrhoids. The symptoms were those of intestinal indigestion, and some cases were cured by proper dietetic treatment and the administration of intestinal antiseptics. Saline laxatives in the morning, especially the phosphate of sodium, would be found beneficial; but in the majority of cases local treatment was indispensable. The aqueous fluid extract of rhatany, in various strengths, acted almost as a specific in this disorder. The extract was not ordinarily kept in stock in the drug stores. It was important to make sure that a resinous precipitate was not thrown down when the extract was added to water. If it did this, the extract was more irritating than soothing, and was unfit for use. If made of a glycerin-and-water percolation and then evaporated until a grain of the extract represented a grain of the crude drug, it would be found a valuable remedy. From one to six ounces of a twenty-five-per-cent. solution were thrown up into the intestine as high as an ordinary bougie would reach. Improvement was usually noted after two or three applications.

Ulcerative Colitis. Dr. Tuttle said that both blood and pus were always present in the ulcerated intestine, but the quantity was so small that it might not be noticed unless carefully looked for. The ulcerations were covered by a thin layer of muco-pus, underneath which was a granular base, with edges sloping toward the centre. The subjective symptoms were marked lienteric diarrhœa alternating occasionally with constipation, impaired digestion, and continued loss of flesh. A positive diagnosis could be made only by inspection of the affected part of the bowel. The treatment should consist in flushings with boric-acid solution and the application to the ulceration of some healing agent, such as argonin or antinosin. The latter should be insufflated.

Follicular Inflammation. In the sigmoid flexure we might find follicular inflammation. The mucous membrane was hyperæmic and showed numerous lit-

dle nodular elevations. There were numerous minute ulcerations associated with a moderate secretion of mucus. These patients rarely had a satisfactory stool, but went to the closet several times a day. They suffered from flatulence and digestive derangements, and found very little relief from the usual remedies for constipation and indigestion.

Morning Diarrhœa.—In the opinion of the speaker the so-called morning diarrhœas were always due to some organic disease of the rectum, sigmoid, or descending colon, particularly of the first two. It might be cancer, polypus, papilloma, ulceration, or catarrhal disorder, but in every case he had been able to find some irritating condition to account for the diarrhœa.

Mucous Diarrhœa.—This was another condition due to actual disease. It was always associated with a follicular inflammation of the sigmoid flexure and colon, and was frequently seen in connection with atrophic catarrh of these parts. The colicky pains occurring after stool were due to temporary obstruction from spasm and masses of mucus. The nervous symptoms associated with this disorder seemed to be a part of the affection, and not its cause.

Technique of Rectal Examination.—Dr. Howard Kelly, of Baltimore, sent a paper on this subject, which in his absence was read by Dr. Tuttle. He said that formerly it had been the habit of rectal specialists to limit their examinations to three or four inches, or less, from the anus. In his method of examination, after the evacuation of the bladder and bowel, the patient was put in the knee-chest posture, a cylindrical speculum inserted, and the examination made by direct or reflected light. On the introduction of the speculum the entire lower bowel expanded with air, the valves stood out with remarkable distinctness, and a bright, flat surface was exposed to critical examination. His first examinations, according to this method, were made in 1884, and were suggested by the very satisfactory exposure of the vagina obtained by the aid of the Sims speculum. In his opinion the rectal specialist needs forty or fifty specula of varying sizes.

Dr. Lewis H. Adler, Jr., of Philadelphia, was invited to open the discussion. He said that he had been impressed with the necessity for more accurate work in connection with rectal diseases, and, from the fact that three cases of cancer of the valve had been recently diagnosticated as fistula and hemorrhoids, there seemed to be ample opportunity for enforcing upon the profession the necessity for digital examination of the rectum. Up to the time of the introduction of Kelly's tubes even the rectal specialist was obliged to diagnose diseases of the sigmoid almost entirely without the aid of sight. If there was a discharge of blood, mucus, or pus from the valve, it became the duty of the physician to investigate it. In the vast majority of instances this meant an exhaustive exploration, such as could be made only with the help of Kelly's tubes. When there was constipation there was apt to be more or less disease of the valve. The rectum became congested, first of all, by the pressure upon the blood-vessels by the fæcal masses, and whenever congestion existed there was liability to inflammation, and, later on, to ulceration and stricture. The liability to auto-infection in all cases of chronic constipation should be borne in mind. He had failed to find a ballooning of the rectum, as described by Dr. Kelly as occurring on the introduction of his tubes. The first obstruction commonly met with on the introduction of this instrument was the promontory of the sacrum, although sometimes a misplaced uterus might prove an obstacle. In all inflammations or ulcerations of the valve a fundamental principle of treatment should be to insist upon the patient being kept in bed. The next most important point concerned the diet. It was possible by means of a long curette and a Kelly tube to obtain scrapings of a suspected malignant growth situated high up in the bowel, and thus to determine by microscopical examination definitely regarding its nature.

Dr. Charles B. Kelsey said that every practical worker in diseases of the rectum had recognized the existence of a certain portion of the bowel which might justly be called a *terra incognita*. This portion varied between four and eight inches in length, depending upon the conformation of the sigmoid flexure. If the sigmoid flexure had a curve, it was quite possible to bring the two hands together in making conjoined manipulation, without including several inches of a portion of bowel in which a pathological state might exist. He had not found it necessary to follow the rules laid down by Dr. Kelly. For example, he had found that the examination could be made just as well with the patient lying on the right side as when in the knee-chest position. In his experience the only suitable illumination for these examinations was the direct electric light. He agreed entirely with Dr. Adler, that ballooning of the rectum did not necessarily follow the insertion of the Kelly tube, but he did not find this ballooning of any value in diagnosis.

A Modification of Kelly's Tube.—A practical difficulty experienced with the Kelly tube was that the same part of the anterior, posterior, or lateral wall of the rectum did not prolapse into the tube on successive examinations. He had accordingly modified the Kelly tube by inserting a slide and fenestra in its side. It was really an adaptation of the old Aloe speculum to the Kelly tube. He did not think he had ever been able to make a diagnosis of malignant disease of the lower bowel by the Kelly tube which he had not been able to make by palpation under a general anæsthetic: but he had been able to detect localized ulcerations and polypoid growths higher up in the intestine which had not been discoverable before. He had in this way been able to remove a polypoid growth eight inches from the anus, under the guidance of direct inspection.

The Nervous Connections of the Rectum.—Dr. William H. Thomson said that the number of remote results from persistent and serious rectal irritation was much greater than was supposed by those who have not given special attention to this branch of medicine. He did not question the wisdom of treating many cases of dyspepsia by the rectum rather than by the stomach. In cases of mucous enteritis and mucous colitis we should inspect, by means of the Kelly tubes, the lower part of the intestinal canal. There was an extensive system of reflexes extending from the rectum to the pylorus, as was well shown in every case of dysentery. He had recently had two cases of prolapse of the rectum in elderly persons, which had resulted in melancholia with delusions.

A Fallacy about High Enemata.—Dr. Andrew H. Smith said, regarding the administration of high enemata, that it seemed to him that with the flexible tubes in common use it simply amounted to bending up the tube upon itself just within the sphincter. This might happen without causing such an abrupt bend as to interfere with the flow of fluid. For this reason many supposedly high enemata were really very low enemata.

Dr. H. N. Vineberg said that he had not experienced any difficulty in examining the rectum in women by placing them in the knee-chest position, and he attributed it largely to the fact that he used a very low couch. With the patient in this position he had found that the rectum did balloon out on the insertion of the Kelly tube.

The Treatment of Mucous Colitis.—Dr. Landon Carter Gray said that he had been called upon to

treat seven cases of mucous colitis. In not one of these had the local treatment done any good; on the contrary, it had been painful and had distinctly aggravated the condition. He had cured three of these patients by the use of good and a proper management of the very marked nervous symptoms which were present. The more restricted the diet in these cases, the more did the general nutrition suffer, and improvement was noted strictly in proportion to the improvement in the nervous condition.

The Brain does Not Lie in the Gut.—He had been greatly surprised at the statement made by Dr. Thomson, that he had observed melancholia with delusions dependent upon prolapse of the bowel. He had himself seen a certain amount of mental depression in such cases, but never true melancholia. It was very hard for the neurologist to believe that the brain was located in the gut.

The Lower Bowel Exposed to Traumatism.—Dr. William Vissman said that the sigmoid flexure itself was liable to a great deal of injury. The desire to defecate arose as soon as the fæces entered the upper end of the rectum, but it was often inconvenient or impossible to respond to nature's warning, and hence hard masses of fæces and various undigested particles were compelled to remain in the sigmoid flexure. These hard masses naturally gave rise to more or less traumatism. More than this, the retention of the fæcal masses exposed the gut to the manifold irritating products of decomposition.

Dr. Tuttle, in closing, said that the brain was often potently influenced by diseased conditions in the lower bowel. The cases of mucous colitis that were cured by medical treatment were examples of hypertrophic catarrh, but the other types of mucous colitis were never cured until the local condition had been cured.

A Setback for Rectal Irrigation.—He heartily indorsed the statement made by Dr. Smith regarding the common fallacy about high enemata given with the flexible tube. He had recently introduced a long Kelly tube as high as possible into the rectum, and through this had inserted a thermometer to the height of twenty-five or thirty inches. The thermometer was left at this point, with a string attached, and then an enema of hot water (110° to 115° F.) was administered through a rectal irrigator. Nearly one quart of solution was introduced in this way. Immediately after it was allowed to escape the thermometer was withdrawn. It was found that it registered a maximum of only 99.5° F. From this experiment he was inclined to believe that irrigations with these short rectal tubes did not reach so high as had been claimed.

Knee-Chest Position Not Essential.—Dr. Tuttle indorsed what had been said against the necessity of resorting to that very uncomfortable and undignified position for a woman—the knee-chest position. The rectum was occasionally ballooned on the introduction of the Kelly tube, but not often. There was no air-tight vault here, as there was in the case of the vagina, and hence ballooning rarely occurred.

An Objection to Kelsey's Tube.—The objection to Dr. Kelsey's modification of the Kelly tube was that a pathological growth might easily be caught in the fenestra and be subjected to undue traumatism. Another objection was that such a side view of a pathological state was more apt to mislead than a direct view, such as was obtained at the end of the tube.

The Castor-Oil Plant.—There is no plant, says an English weekly, which animals so detest as the castor-oil plant. A goat will starve rather than eat it, and those destroyers of everything green, the locust and army worm, will not touch it.

Clinical Department.

ANTITUBERCLE SERUM IN TUBERCULOSIS.

By LANDON B. EDWARDS, M.D.,

PROFESSOR OF PRACTICE OF MEDICINE, UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.

In the cases submitted no auxiliary treatment has been neglected (especially emphasizing the value of beechwood creosote by almost continuous inhalation and internal administration), but serum has proven to be an invaluable help. My records stand in round figures as follows: Total number of cases of tuberculosis of the lungs treated with antitubercle serum (Paquin) since January 1, 1896, thirty-five. Total deaths, five. Each of these cases came into my hands in a practically hopeless condition, apparent to the most casual observer. Total recoveries, eleven. By this I mean that bacilli have disappeared from sputa; healthy respiratory murmur has been restored; chest expansion increased from about one inch to two and one-half inches or more; flesh increased to about normal, according to height; appetite for meats restored, not despising pieces of fat, etc. The patients look well, and, according to physical signs and symptoms, are well. Two other patients, who came under my care after grounds for hope were gone, will die shortly. As to results in two other cases, well advanced in consumption, I am doubtful—to-day apparently improving; to-morrow worse, fluctuating in condition. Three or four other patients are holding their own, inclining to improvement, thus encouraging hope. The other patients are improving, and some, I believe, will recover.

In this estimate I have referred to some patients who are not now under personal observation, living at distant points, but from most of whom I hear occasionally. They are under the care of their home physicians, who, I believe, follow out the general line of treatment advised.

This record is greatly better than I ever had by any other agents than serum. I have used no other serum than Paquin's, being pleased with the results, except in several instances of apnœic attacks alarming the patient, nurse, and doctor, but without any fatality. The rectal method would probably avoid this unpleasant feature in sensitive patients.

106 West Grace Street.

SIMULATION OF DEAFNESS IN A CHILD OF NINE YEARS.

By E. L. MEIERHOF, M.D.,

NEW YORK.

Simulation in various forms in children, especially in girls, is occasionally met with, and is usually intended for the purpose of exciting pity or sympathy, or else to shirk some unpleasant duty.

A few days ago a boy of nine years was brought to me at the throat and ear department of the Mount Sinai Hospital Dispensary, for the treatment of deafness, which seemed confined principally to the left ear. An examination of the ears really showed some changes in the membrana tympani due to catarrhal disease, but upon subjective tests the boy denied hearing the sound of a loud-ticking watch upon contact with the deaf ear; the entire series of Hartmann's tuning-forks were used with the same negative results; speech both loud and whispered was answered in like manner; and finally Galton's whistle was brought into use, but the boy still denied hearing with this ear, whereas hearing on the right was very good. The right ear during the examination was sealed with the tip of the forefinger, passed into the external auditory canal.

There being no history of any previous injury or severe illness—such as meningitis, scarlet fever, or diphtheria—I became nonplussed, until one of my assistants thought he observed the boy giving an answer which appeared to indicate that he heard me when I spoke to him. I attributed this to the interpretation he obtained from the movements of my lips, and when I spoke to him with his eyes closed he still acted as though he did not hear, until I asked him in a low voice whether he wanted ice cream, and other questions of a like character, when he suddenly gave himself away. In a short time he collected himself when he found he was detected, until finally I threatened to operate on his ear, and this proved to be the straw that broke the camel's back. After this I had no trouble in obtaining correct answers, and I thereupon satisfied myself that the boy had good hearing in the left as well as the right ear. His mother, who was present during the examination, could not explain the cause of her child's actions.

57 East Sixty-Fourth Street.

DISEASE OF THE EYE DEPENDENT UPON DISEASE OF THE NOSE.

By TALBOT R. CHAMBERS, M.D.,

JERSEY CITY,

OPHTHALMIC SURGEON TO THE CITY AND TO CHRIST HOSPITALS.

It is well-known history that the removal of a diseased tooth has been followed by relief of various neuralgias; that with the cure of ovarian disease has disappeared a train of symptoms in distant regions of the body; that when an error of refraction has been corrected many unexplainable symptoms have subsided. These conditions have been termed reflex.

With regard to the nose; its near proximity to the eye and its very intimate relationship, by reason of the nerve and arterial and venous connections, remove many, perhaps most, concomitant diseases of these organs from the reflex class. They are, and should be, called direct sequences, the one of the other. The only wonder is that this fact has been for so long a time time unrecognized. Of course there may be disease of the one organ, the other remaining normal. There is no doubt that very often the disease of the one was dependent upon the non-diagnosed disease of the other, and all treatment has proven unsuccessful or at best only palliative.

The nasal branch of the ophthalmic division of the trifacial, after passing through the sphenoidal fissure to the inner wall of the orbit, gives off the infratrochlear nerve and leaves the orbit by the anterior ethmoidal foramen. In the orbit it contributes the long root to the ciliary ganglion and also the long ciliary nerves which go to the iris. The infratrochlear supplies the lacrymal sac and the skin over the inner corner of the eyelids and the adjacent side of the nose. The root of the ciliary ganglion, which is derived from the nasal nerve, is its sensory root. The short ciliary nerves from the ganglion are distributed to the ciliary muscle and iris. The ophthalmic artery supplies both organs.

Is it any wonder, then, that an operation upon the interior of the nose causes weeping from the eye of the same side? Is it any wonder that disease of one side of the nose will unbalance the normal condition of the neighboring eye? If a temporary interference causes immediate disturbance, how much more is it to be expected a chronic nasal disease will be the source of chronic and serious eye trouble.

It is on this account that the ophthalmologist who recognizes this close relation will more nearly and more often succeed in affording relief to his patients than one who never seeks elsewhere for the cause than in the complaining member alone.

"That's the very pain I used to have," said a patient (Dr. V.) to me, just as I was excising a partial deviation and exostosis of the septum. "That is the pain for which Dr. X., of New York, cut the muscles of my eyes a number of times. Dr. Y. said I should be compelled to endure as best I could, for it could not be relieved." Both of the gentlemen referred to are men of the very highest professional standing—men whose ultimatum is considered final. In this case the relief of the undue pressure of the deflected septum against the inferior turbinated bone caused a disappearance of all the eye symptoms, and the patient is free from a martyrdom which was a continual source of annoyance and an interference with his work. It prohibited any prolonged near use of his eyes and rendered him apprehensive and nervous.

A second case is that of C. C—— suffering with chronic glaucoma. When he came under my care he had declined having one eye removed. This proposition had been advanced when the disease was limited to the single eye. Now both eyes were in a state of plus tension. The removal of a cartilaginous spur of the septum, which had been pressing continuously and increasingly upon and into the inferior turbinated, immediately relieved the pain and unrest of the eye of the same side, and the eye shortly came to a state of rest. Of course the results of the damage already done remained. But the improved condition of both eyes may, in my humble opinion, be ascribed to the relief of the abnormal nasal condition.

A third case is one in which possibly choroiditis was a direct result of compression within the nares. It may not be asserted positively, but the inference is very strong. A young man (C. L——) with necrosis of the right palatal bone and of two pieces of bone of the superior maxillary at the floor of the antrum and nostril had choroiditis on the same side. For several years his right antrum and nostril had within them a chaotic condition of affairs. A large quantity of secretions was locked up, and though there was but little pain the eye of that same side was constantly in a state of unrest. After the parts were cleared out and the three bones were removed, and by the aid of a cleansing douche the large chamber was put in a healthy condition, the eye came to rest. The vision was not recovered, but the inflammatory state was aborted and stopped.

Again (A. S——), with polypus of the left middle turbinated causing obstructive symptoms. The eye was markedly in trouble, though no pathological changes were apparent with the ophthalmoscope. Yet externally it showed irritation, and the patient sought professional help for his eye and not for his nose trouble. After the polypus was snared off no treatment was necessary for the eye.

Other cases could be cited, but these show conclusively the direct relationship between an abnormal condition of the interior of the nose and antrum and serious eye disease. In none of the cases cited could the patient use the eyes an hour continuously for near work without fatigue, and they were all incapacitated for continuous work of that nature. Relief of the nasal pathological abnormalities produced relief of the eye symptoms in each case.

Pressure of a septal spur, of a deflected septum, or of a hypertrophied turbinate, an ethmoiditis, or even an advanced condition of catarrhal rhinitis is accompanied by eye symptoms, or rather is the cause of disease of the eye. The symptoms vary in degree. The eye symptoms treated alone will always be but partially relieved. Some cases of fascicular keratitis will never be cured while the rhinitis accompanying remains unattacked. Besides eye fatigue and eye

pain on continuous use of the eyes, such serious diseases as fascicular keratitis, glaucoma, and choroiditis are so frequently seen with nasal complications that it does seem pertinent to claim—that no eye patient should be prescribed for until nasal and antrum complications have been corrected. Then only will ideal results be accomplished.

UNUSUAL ANATOMICAL CONDITIONS DISCLOSED BY ABDOMINAL SECTION—A REPORT OF THREE CASES.

By HOWARD LILIENTHAL, M.D.,

ADJUNCT ATTENDING SURGEON TO MOUNT SINAI HOSPITAL, NEW YORK.

The cases here reported are of interest principally because of their complication by anatomical conditions, the existence of which could hardly have been guessed before their disclosure by means of the knife.

Case I.—H. G——, a man, forty-six years old, came under my observation the 21st of last May, in Mt. Sinai Hospital. The diagnosis of his physician had been appendicitis, arrived at, rationally enough, from a history of constipation followed by sudden and severe pain in the right iliac region, accompanied by fever, nausea, rapid pulse, and the appearance later of icterus, together with general abdominal tenderness and distention. When I first saw the patient he had been sick for two days, and he had the appearance of one suffering from general peritonitis. The whole belly was sensitive and there was especial tenderness at a point just within the right anterior superior iliac spine. The temperature was 101° F., and the pulse 100 and of good quality. The extremities were cold and the man's facial expression was anxious. Dr. G. E. Brewer, who saw the patient with me, called my attention to the fact that one could feel, on rectal examination, a rather tense bulging at the right side. Further questioning brought out the information that there had been no stool for two days in spite of the internal administration of cathartics.

As we concurred in the working diagnosis of appendicitis and recognized the desperate state of affairs, the man was at once chloroformed and a five-inch incision was made in the right side, as if to expose the appendix. An enormous, tense, black, tympanitic mass was disclosed, which only on careful and minute inspection was recognized by faint longitudinal striation as large intestine. The incision was now lengthened in such a direction as to form a crescent, nine or ten inches long, with the umbilicus just within its horns. Through this large wound it was now possible to examine and raise up the huge coil of gut. Behind it were seen, quite empty and pushed well backward, the normal cæcum, appendix, ascending and transverse colon. The small intestine was distended, but not to an alarming degree. There was no peritonitis.

The great coil of large intestine, now recognized as an abnormal sigmoid flexure, was lifted out of the abdomen and was seen to be a volvulus, the twist being one of one hundred and eighty degrees. The seat of the twist, where the ends of the loop came together, was in the left iliac region, where there had been little if any tenderness, the most sensitive point, as already remarked, having been on the right side. The gut was easily put back into its normal relations, completely reducing the twist, but the intestinal wall seemed quite paralyzed and gave no sign of peristalsis. The involved portion was truly gigantic; it was hypertrophied as well as distended. It was as large as a man's thigh, Dr. Brewer and I estimating it as at least eighteen inches in circumference. The coil, too, was very heavy, being half filled with liquid fæces. I punctured the wall, evacuating considerable gas, and still the intestine was too large to be safely replaced into the abdomen. Considering the case a hopeless one, I cut a hole in the sigmoid, about an inch long, allowing the escape of several quarts of fæcal matter. The coil was then easily placed within the belly, and the openings were sewn up. The abdominal wound was closed at the ends and left open in the middle, the sigmoid having been stitched to the belly wall at this point, so that those parts of the gut which had been opened remained in the wound to be in a safe place in the event of leakage.

To my surprise the man made an almost uneventful recovery. A pinhole fæcal fistula occurred four or five days after the operation, but soon closed spontaneously. Secondary suture was performed to hasten the closure of the abdominal wound, and the patient was discharged from the hospital, well, about seven weeks after admission. He was presented by me at a meeting of the section on surgery of the New York Academy of Medicine on October 11, 1897.

This case was probably one of chronic volvulus, the twist having become completely obstructing at the time the acute symptoms came on. This is the only way to account for the great hypertrophy of the sigmoid flexure. The abnormal length of this part of the gut, too, is well known as a predisposing cause for volvulus. After reduction of such a twist, suture of a portion of the involved intestine to the belly wall is said to guard against recurrence of the trouble.

My experience with the man whose history has just been related was of value in the management of the following case:

Case II.—On September 9, 1897, Mrs. P. S——, twenty-six years old, the patient of Dr. J. F. Lyon, was stricken with appendicitis. The symptoms were at first mild, but by the morning of the 11th, two days after the onset, a sudden rise in temperature to 103° F., with corresponding cause for alarm in the patient's general condition, decided Dr. Lyon to regard the case as one for operation. I saw Mrs. S—— the same morning, and, agreeing as to the advisability of operating, we determined upon immediate action. The operation was performed a few hours later.

On making the incision, under chloroform, through the very fat abdominal wall, a gush of turbid serum justified our haste. A coil of large intestine, easily recognized by its size and its anatomical markings, came into view. Following the lower portion of the coil, I found that it was very long and extended to the left. The upper portion could be followed to the liver and then to the left. It was not attached to the liver and came out of the abdomen more easily than is usual with the normal ascending colon. It was then that the condition of things in Case I. came to my mind, and I suspected that the coil of intestine with which I was dealing might be the sigmoid flexure. Accordingly, it was held aside and, sure enough, far in the posterior part of the flank was the ascending colon. The cæcum and appendix were held by dense adhesions upward, inward, and backward, almost under the umbilicus, a state of things for which a vague history of a former attack may suggest an explanation. It was not possible to shell out the appendix, so I ligated its base and removed the gangrenous organ piecemeal. The entire neighborhood of the appendix was thoroughly flushed with peroxide of hydrogen, which I believe to be a powerful local stimulant by reason of its oxygenating power, and the wound was closed except at one point, through which a thin slip of gauze was led out from the bed where the appendix had been. Silkworm-gut sutures were used through peritoneum, muscle, and fascia, the skin with its very thick panniculus adiposus being left unsutured to close by granulation.

The patient made a most satisfactory recovery, the entire wound except the drainage hole being closed in a little more than four weeks. None of the silkworm-gut sutures came away and the sinus is now also entirely healed.

The third and last case to be reported here is of interest on account of an anatomical curiosity. It would have been impossible to diagnose the condition before operation.

Case III.—L. R——, thirty-four years old, entered Mt. Sinai Hospital on April 27, 1897. Four days earlier his sickness began with severe abdominal pain, at first referred to the epigastrium and later spreading to the entire belly. Soon after the onset persistent vomiting began. A small inguinal hernia was noted first during the four days mentioned, but it was reducible and not tender. In spite of cathartics there had been no evacuation of the bowels during the entire time, and when I saw the patient his abdomen was distended and tympanitic, his pulse was 96, his temperature was 100.2° F., and his respirations were 29. Vomiting was still unchecked and he was becoming exhausted. No mass or tumor could be felt on palpation.

There being evidently intestinal obstruction to deal with, operation was at once decided upon. Even under the chloroform nothing could be ascertained which might give a hint as to the best place for the incision, so I first cut down on the hernia, reducible though it was. No sign of strangulation being found here, I closed the wound and made a second incision in the right semilunar line, with its centre at the level of the navel. The intestines were deeply injected and through the wound I felt what I took to be an adhesion. Enlarging the wound, I found that what I had taken for an adhesion was the thick edge of an enormous slit in the mesentery of the ileum. Through this opening about two feet of ileum and a large knuckle of ascending colon had slipped, causing strangulation and complete intestinal obstruction. The strangulation was not of a severe grade, however, no gangrene being present. This internal hernia was easily reduced and I sewed up the mesenteric slit with a continuous catgut suture. The anæsthesia was a long one, nearly two hours, and the patient's condition such as to require free stimulation.

The vomiting practically ceased after the operation, but the patient died of exhaustion twenty-four hours later, his bowels not having moved.

The post-mortem examination revealed no other points of strangulation or obstruction.

679 Madison Avenue, New York.

INFANTILE SCURVY.

By G. S. DeGroute, M.D.,

Mendham, N. J.

Pending the report of a collective investigation of infantile scurvy in North America, by the American Pediatric Society, I desire to report a case which is instructive by reason of the absence of most of the symptoms as stated in the text-books.

A female child, nine and one-half months of age, never previously ill and a picture of health, of good family history, living amid perfect hygienic surroundings, was taken with pain in the right knee and hip, noticed only when certain movements were made, as when the nurse changed the napkin or made extension of the leg. Pain was not caused by pressure on either of the joints. Within twelve hours the pain was manifest also in the left shoulder and ribs, and soon after in the other limbs and the pelvis, although it was worse in the left arm and leg. There was only a slight swelling of the knee-joints; there were no fusiform swelling of the lower extremities, no heat in the parts, no rise of temperature, no ecchymoses until late in the course of the disease, no spongy or bleeding gums—in short, none of the symptoms of infantile scorbutus, except the pain on motion.

In a conversation with my friend, Dr. A. E. M. Purdy, of New York, I related the case to him, and he said he thought it a case of infantile scurvy. I objected on the ground of lack of symptoms. He replied that he had met just such a case in his own practice. I asked him to see the child with me, which he kindly did, and the treatment proved his diagnosis correct.

The details of the child's feeding from birth are as follows: Was fed at the breast for ten days after birth; then given modified milk until four and one-half months old; but as the child did not gain in weight as it should, it was put on the following mixture: milk, barley water, water, of each two ounces; lime water, one teaspoonful; sweetened to taste with milk sugar and pasteurized. This mixture was made stronger by increasing the quantity of milk and decreasing the water, until it was half milk and half barley water; then the barley water was made thicker, until it was like jelly. For a month before the scurvy appeared the child was taking at a feeding six ounces of milk and barley jelly, equal parts. As soon as a diagnosis was made I stopped the pasteurizing, but continued the milk the same strength as before, and gave the juice of half an orange the first day, then of a whole one afterward. I also ordered beef juice, but it was not digested, so I did not continue it. In forty-eight hours after the orange juice was commenced there was marked improvement, and in four days the child was well.

HEALTHY OFFSPRING OF SYPHILITIC PARENTS.

By JOHN H. BILLINGS, M.D.,

New York.

It is interesting to notice at times the remarkable immunity the unborn child enjoys from syphilis, even when both father and mother have the disease in its active form during the entire term of pregnancy. The case in point, a good illustration of the foregoing statement, presented the following:

A. B——, about one year after marriage, contracted syphilis from an outside source. On his presenting himself to me, I found a large indurated chancre on the dorsum of the glans penis, a well-marked roseola, mucous patches on the tongue and inner wall of the cheek, besides several small condylomata at the margin of the anus. It was a well-marked, active case of syphilis. He was put at once on appropriate treatment and soon commenced to show a decline in the symptoms.

A month elapsed, when one day he brought his wife, who, entirely innocent, had contracted an indurated chancre on the left labium majus. She presented a syphilide (papular) on the chest and back, mucous patches on the tongue and soft palate. Under treatment these symptoms soon commenced to decline. She became pregnant about this time, and vigorous treatment was pushed up to the point of mild mercurialization. The pregnancy went on to full term, the child, a fine boy weighing nine pounds, not presenting the slightest symptom. He is now in his fourth year, physically and mentally perfect in every way.

The desire of the husband to keep his infidelities a profound secret made the task of treating the wife an extremely difficult one. Her condition could not be explained to her in a very satisfactory way, and when all symptoms disappeared and her health was seemingly restored, my efforts to have her take treatment

for the period of two years caused no little anxiety on my part, and various excuses were thought of to bring about this end. However, everything went well. Within a year another child was born to this interesting couple, a healthy girl.

UTERINE FIBROIDS SIMULATING PREGNANCY.

By JOHN S. PYLE, M.D., LL.B.,

CANTON, OHIO.

On two occasions in my surgical practice I have met with cases in which uterine fibroids gave rise to symptoms simulating pregnancy. In the case that I shall particularly refer to in this article, the symptoms and signs of pregnancy were so marked that it was impossible to state positively that pregnancy did not coexist.

The patient, at the time of her marriage, was thirty-six years old, and presented a pair of undeveloped breasts and a body thin in flesh, with almost an absence of adipose. She gave a history of menstruating freely and regularly from the period of her fourteenth year, the menstrual flow lasting from eight to ten days. At the time of her marriage nothing unusual was noticed about the size of her abdomen, but soon after an enlargement was discoverable in the region of the hypogastrium, which kept increasing in size, and, as the breasts showed signs of development, with a marked increase of bodily weight, the family physician felt justified in assuring the patient that she was pregnant. The monthly discharges kept up regularly and became more profuse, amounting at times to serious flooding and loss of blood, but this was interpreted to signify an abortive tendency, and the patient was instructed to observe quietude and remain in bed. Each succeeding month brought the usual alarming hemorrhage; the breasts kept on enlarging, the areolar rings widening and becoming deeply pigmented; the bodily weight correspondingly increased, the adipose showing a selective tendency for those regions so characteristic of pregnancy; and, lastly, the breasts filled with a milky fluid which was thought to prove beyond a doubt that the woman was pregnant. Two physicians were committed in expressing the opinion of pregnancy, and, while they agreed upon the finding, they disputed with each other on the exact time when the birth should take place. This caused the patient to delay from month to month any further consultation, and it was twelve months from the first notice of the enlargement until I was called in the case.

Upon examination and interrogation I found her condition and history as detailed above. The abdominal enlargement, instead of presenting a regular contour, was very irregular; the growth extended markedly to the left side and was nodulated; some of the protuberances had grown to the size of a fist, and were easy of detection. The upward extension reached a point above the level of the umbilicus, and, owing to the inherent weight of the growth, it tipped forward, making the abdomen appear very prominent. Its unyielding character, with the history of profuse and prolonged menstrual discharges, rendered the diagnosis of fibroids comparatively easy; but it was impossible to be so certain that pregnancy was not a concomitant, thereby accounting for the history of rapid development and the other changes of pregnancy narrated above. Indeed, one would, with such a history, be inclined to believe in the coexistence of pregnancy. A digital examination, however, revealed a hard mass in the pelvis continuous with that found in the abdominal region. Nothing was found, by palpation, to indicate a pregnant tumor. Under such circumstances, with the history of a growth of short duration, it was impossible to exclude to a certainty the existence of a non-viable pregnant mass surrounded by a fibroid development. In this mental attitude I was content to rest until I satisfied myself through a surgical operation of the true condition. Three days from the first examination I completely and successfully removed the growth, which was as large as an ordinary-sized man's head, and consisted of the uterus, with numerous centres of fibroid development throughout its entire walls and a large developmental hypertrophy of the muscular substance of the organ.

Now the question arises, Is the history of this rapid enlargement to be entirely discredited, or are we to give full credit to this history and account for it on the ground of a rapid muscular hypertrophy causing the attendant symptoms and signs of pregnancy? This latter would seem to be a rational explanation. Upon this point and of similar cases I should like to hear from the experience of others.

Let me add that the patient made an uninterrupted recovery and still retains her adipose and large mammary development. There seems to be no alteration in her nutrition, and her weight remains about the same.

505 South Market Street,
December 2, 1897.

FOREIGN BODY IN THE RECTUM.[1]

By ANTONIO MATIENZO, M.D.,

TAMPICO, MEX.,

CHIEF SURGEON TO THE CIVIL HOSPITAL.

It is well known that foreign bodies in the rectum are classified into three categories: 1st, those formed in the intestine; 2d, those that, having entered by the mouth, remain at the extremity of the intestine; and 3d, those that have been directly introduced through the anus. To this last category belongs the present case. It would be superfluous to specify the great number of objects that have been found in the rectum. It is sufficient to name, among the more notable cases, the red-hot iron bar which the tormentors of Edward II. of England introduced into his intestine; the case of Nélaton, who observed a man who in drunken revelry introduced into himself a big drinking-glass; that of Desormaux, who reported the extraction from the rectum of a bottle, nineteen centimetres long by five and one-half centimetres in diameter; and many others of pieces of wood, stones, etc. The case which I am about to report is also interesting because of the extreme length of the foreign body, the time it remained in the intestine, and the fact that it did not cause any rupture of the gut.

Vreneo Ram, thirty-six years old, a laborer, came to the Civil Hospital, October 1, 1896, complaining of severe pains in the stomach, a frequent desire to go to stool, and intolerable tenesmus, with nearly complete retention of fæcal matter and continual passage of blood. He stated that he had been sick since the 16th of September last, and did not know what could be the possible cause of this sickness, remembering only that on that date he was intoxicated to the extent of being unconscious.

On examination of the patient and simple inspection of his abdomen, a tumor as large as a nut appeared, located at the left and very near the umbilicus. It was hard to the touch, easily displaced by pressure, and returned to the same place upon discontinuance of the pressure.

On rectal examination, about three or four centimetres from the anus, the finger touched a hard and irregular body, which moved upward and seemed to be the lower extremity of the tumor felt above, judging from

[1] Paper read before the Mexican National Medical Academy.

the movement given and transmitted to it by conjoined manipulation. Displaced to the right and pushed upon at the higher extremity, it showed at the anus and was easily extracted.

As the patient could not remember anything throwing a light upon how the accident happened, I believe that, while he was dead drunk, some person—a friend (?) perhaps—with ill intentions or as a joke, introduced the foreign body. It was a piece of wood of uniform diameter and polished; the extremity that went in first was semispherical and polished; the lower extremity, irregular with edges and sharp points, was resting on the rectum. The stick was twenty-six centimetres long by six centimetres in diameter, round, and, as I said before, was in the intestine from the 16th of September till the 1st of October, causing an incomplete intestinal obstruction and proctitis of slight intensity.

A CASE OF RHINOPLASTY.

By PATRICK CASSIDY, M.D.,

VISITING SURGEON TO THE W. W. BACKUS HOSPITAL, NORWICH, CONN.

RHINOPLASTY is probably the oldest of skin-grafting or plastic operations, so another article on the subject seems superfluous. Yet I venture to report this case

FIG. 1.

on account of the method of preserving the shape of the nose. The clinical history of the case is as follows:

Mrs. P——, aged seventy, had, four years ago, a pimple on her nose. She was in the habit of picking and in other ways irritating it. At first there was not much increase in size, but it did not heal. She then applied various washes and ointments. In January of last year there began a rapid increase in the size of the ulceration, until at the time of her entrance to the hospital the ulceration had extended over the anterior superior surface and sides of the nose, exposing the cartilage and also the ends of the nasal bones. The ulcerated area was one inch in diameter. No glandular enlargements were made out. A diagnosis of malignant disease was made and an operation decided upon. This was performed on May 28, 1897. An incision was made around the ulcer, about two centimetres from its margin and including all the indurated tissue. Portions of the cartilages were removed. On the right side the disease was found to have eroded into the vault of the nasal cavity. This was thoroughly curetted. Silver-wire sutures were passed through the remnants of the alæ and through the septum of the nose. A horseshoe flap was taken from the infra-orbital space of the right side and from the fore-

FIG. 2.

head, twisted, and laid on the nose. This flap received its nutriment through a pedicle attached to the cheek. Now the silver-wire sutures, mentioned above, which were to act as retention sutures to hold the nose in shape and close the opening in the right nostril, were secured by shot impinged on the wire. Cork washers were interposed between the shots and the nose. The flap was then securely sutured by interrupted sutures of silk. After three days the retention wires were removed. On the tenth day the slight eminence caused by the half-twist in the flap was trimmed off. The healing was uninterrupted, save for a slight development of pus. Upon the observance of this, the Labarraque wet dressing was applied, and after two days the pus had disappeared. Twenty-two days after the operation the patient was discharged, the wound having healed. Since then she has been seen several times. She looks many years younger and is now able to read, a thing she was unable to do before

FIG. 3.

the operation, because she could not make her glasses stay on.

The accompanying cuts show her change in appear-

ance. Fig. 1 shows the appearance of the patient on entrance to the hospital; Fig. 2, the appearance two days after the operation. The shots can be seen near the edges of the wound. Fig. 3 shows the patient after discharge.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LATE SIR RICHARD QUAIN, M.D., LL.D., F.R.S.—GASTRIC ULCER—MALFORMATIONS AND DISPLACEMENT OF KIDNEYS—WOUNDS OF THE KNEE-JOINT—COLLEGE OF SURGEONS—EPIDEMICS—INTRACRANIAL DRAINAGE FROM CHRONIC HYDROCEPHALUS—PROGRESS OF GYNÆCOLOGY IN THE LAST TWENTY-FIVE YEARS—URIC ACID IN THE BLOOD—THE LATE DR. WEST, HON. PHYSICIAN TO THE QUEEN.

LONDON, March 18, 1898.

SIR RICHARD QUAIN died on Sunday and was buried on Wednesday. Your readers will have been prepared for this news by what I have previously stated as to his health. They will perhaps know him best as the editor of "A Dictionary of Medicine," which is a veritable cyclopedia in one volume of more than eighteen hundred pages in double columns. This was issued in 1883, and several thousands were sold. A second edition was published in 1894. Sir Richard gathered round him a very able staff for this work, and, though each contributor enjoyed a tolerably free hand, he by no means took his editorial work lightly. He read carefully every article, and of course the work was a long time on the anvil. He said to me on its publication that it was a great relief to have it finished, for he reckoned he had given ten years of his life to its production.

On this side we know him more as the genial, successful consultant, president of the Medical Council, and chairman of the pharmacopœia committee. His interest in the pharmacopœia never flagged, and it is almost pathetic that at the last meeting of the executive committee the final proofs were produced and the order was given to go to press. Sir Richard Quain was elected a fellow of the Royal Society in 1871. Last year he read before that society a paper on the mechanism of the first sound of the heart—a disputed subject which I do not think his paper tends to settle. He had always felt great interest in diseases of this organ. As early as 1845 he contributed a paper on injury to its valves to the *Edinburgh Medical Journal*, and his Lumleian lectures (1872) were devoted to diseases of its muscular walls. He had in the mean time contributed papers on this organ to the societies. Naturally in his dictionary some of the articles dealing with cardiac disease were from his own pen.

Sir Richard Quain was vice-president of the College of Physicians in 1889, before which he had received all the minor honors of the college and several honorary degrees and other compliments. He was appointed by the Crown a member of the Medical Council in 1863, and has been reappointed after each period of service. He was for many years treasurer, and in 1891 was elected president. He became physician extraordinary to the Queen in 1890, and received a baronetcy in 1891.

The name of Quain is an honorable one in medicine. Jones Quain, the anatomist, and Richard Quain, the surgeon, were cousins of the late physician, and some amusing confusion occasionally occurred on the part of the public between the two Richards. The surgeon died in 1887, and some of the newspapers announced the death of the physician. Even now some papers have produced portraits of the surgeon to illustrate their obituaries of the physician.

On Monday Dr. Seymour Taylor at the Medical Society meeting maintained the view that acute and chronic gastric ulcers are essentially different conditions and not, as many still hold, different stages of the same disease. In this view he can certainly claim the support of many clinical observers. He looks upon the acute or perforating ulcer as due to a neurotic lesion. He urged that even after perforation occurred there was hope of success from surgery, and that patients should not be left to die for want of a laparotomy.

Dr. T. Williams held that gastric ulcer and chlorosis were both due to a low condition of the general health, and questioned the common opinion as to the relation between these diseases—one being very common and the other rare. So with regard to anæmia and chlorosis so often attributed to constipation: they are less frequent in France, where constipation is almost the rule.

Dr. Maguire remarked that in chlorosis there was a rapid bodily development with which the blood-forming function failed to keep pace. In this state iron was useless unless in combination with arsenic. The latter was known to exercise an important influence on other anæmic states. He thought the stomach was in those cases rendered susceptible by the lowered vitality of the system.

Dr. Bowles remarked on the association of rheumatism as well as anæmia with gastric ulcer, and thought that chlorosis arose from overwork during a critical period of development. This being so, the indication for treatment was complete rest under proper hygienic conditions.

Mr. Wallis remarked that in chlorosis superficial slight injuries were slow to heal and perhaps the same was the case in the stomach. He supported the author's advice not to delay calling in the surgeon.

Dr. Sansom said it was difficult to understand why a general condition should produce a lesion in one organ and limited to one tissue of that organ, even to a limited part of that tissue. He suggested as a cause some tropho-neurosis producing a vascular contraction and so necrosis.

Dr. Taylor in reply admitted that rest of body, mind, and stomach was the best treatment. When vomiting was prominent he resorted to nutrient enemata. He was favorably disposed to the oxygen treatment. He thought mechanical injury did not produce an ulcer, and remarked that those who swallowed knives and other substances did not have gastric ulcer because they were men and not young girls.

At the Clinical Society's meeting Dr. David Newman, of Glasgow, read a paper on malformations of the kidney and displacements without mobility. Of the latter some were congenital and might be with or without deformity. The others were acquired. Under malformations he placed variations in number, size, and form. He further referred to anomalies in the pelvis, ureters, and blood-vessels. Cases were cited of each variety of malformation and displacement.

Mr. Howard Marsh mentioned a case of tuberculous disease of the kidney, found in an exploratory operation. The tuberculous granulation tissue was scraped away and the patient recovered and is now well, four years after the operation.

Dr. Cheyne said that in January he cut down on a swelling in front of the bladder and found a third kidney; the other two he satisfied himself were present in the usual places.

Mr. Wallis then related three cases in which the knee-joint had been perforated, to show that only those cases running an aseptic course recovered which were treated immediately, and that on the whole it was bet-

ter to dispense with drainage. Even prolonged suppuration did not necessarily mean ankylosis if treatment was carefully carried out.

Mr. Marsh said that in these days we saw how closely synovial membrane resembled peritoneum in tolerating aseptic operations. He had opened a knee-joint four times in one case of sarcoma; in another case four times for tubercle, scraping out the granulation tissue. He mentioned other cases, showing how active interference in joints had developed of late.

Mr. Barker, too, thought drainage had often been overdone and in recent cases he had not used it, though in septic cases some drainage might be advisable.

Mr. Cheyne protested against washing out cavities with antiseptics. If a joint was wounded he incised it freely, sponged the soft parts around the wound with pure carbolic acid, and drained for from twenty-four to forty-eight hours. Then if all was going on well he removed the tube.

At a meeting of the council of the College of Surgeons a petition of certain fellows and members was read, claiming the right of electing the representative of the college in the general Medical Council, and asking that arrangements should be made for holding such an election. The secretary was instructed to inform the petitioners that the questions raised by them were under consideration.

This is really wonderful, but it is a long way yet before the council gives up its usurpation of the right to appoint the representative.

Middlesborough is still afflicted with small-pox. From eight to twenty-one cases have been notified on the different days of the week.

London has an epidemic of measles.

London, March 25, 1898.

Intracranial drainage for chronic hydrocephalus has been brought before the Clinical Society by Dr. Sutherland and Mr. Watson Cheyne. They showed a patient operated on three weeks previously in whom extraordinary diminution of the skull had followed, though they scarcely ventured on a favorable prognosis as to the child's life. But Mr. Cheyne said if they could operate early enough, before the brain had been injured by pressure, the removal of that pressure might permit development.

They related another case which had steadily improved for three months and then terminated fatally. It was that of a child of six months. The bones of the skull were widely separated and the vertex was occupied by a membrane, nine inches across at the widest point. The operation consisted in making a small opening in the dura mater, opposite the left lower angle of the anterior fontanelle, and introducing a catgut drain, one extremity of which was passed between the dura mater and the brain, for a distance of one inch, and the other pushed through the substance of the brain into the expanded lateral ventricle. A very small quantity of fluid escaped, the wound in the dura mater was closed with catgut sutures, and the scalp wound sewed up and dressed in the ordinary way. Steady improvement followed, but three months later basilar meningitis supervened. At the post-mortem the membranes at the base were thick and adherent and a considerable quantity of fluid was present in the subdural space. The treatment was founded on Dr. Leonard Hill's experiments, and it was hoped that whatever fluid was secreted would pass to the subarachnoid space and be absorbed, thus relieving the brain from pressure.

Mr. Boyd raised the question whether intracranial drainage was likely to be permanent, and noticed that in the account of the post mortem it was said the strands of catgut adhered to the dura, so if the catgut was absorbed the communication might be closed by adhesion of the brain and dura. Dr. Sutherland replied that when some obstruction took place the pressure of the fluid would rise and force a passage. To such a circumstance he attributed a rise of temperature in another patient operated on three weeks ago and who was now brought for the inspection of the society.

Dr. Playfair gave a farewell lecture at King's College. He retires after twenty-five years of service at the college and hospital. He discoursed on the progress of obstetrics and gynæcology during that period. Of course antiseptics loomed largely in this review, but room was found for condemnation of certain views, such as those of Henry Bennett, Graily Hewitt, and others, which have now for some time been abandoned. Coming nearer our times, he entered a caveat against Professor Sinclair's address at Montreal. This, however, he announced would be fully dealt with in the new edition of his book on midwifery. Another topic he took up was the right, I might almost say the necessity, of gynæcologists being surgeons. There has always been in the surgical branch a little jealousy of the obstetricians, but it has been useless, and, although Dr. Playfair talked of a little cloud no bigger than a man's hand being now visible on the horizon, I do not anticipate a storm. Dr. Playfair also referred to the position of his specialty in the Royal College of Physicians.

On Tuesday Dr. Haig gave a demonstration of the chloride-of-ammonium process for the microscopic detection of uric acid in the blood. Dr. Luff objected that no proof whatever was given that the granules found consisted of uric acid or urates. He held that we should not state uric acid to be present unless proved by the only infallible test known—the murexide test. Many had shown that the blood of oxen, sheep, pigs, turkeys, geese, and fowls, as well as of normal human beings, was free from uric acid. Dr. Haig replied that he had not asserted that the granules were either uric acid or urates and he did not know what they were, but thought some of them might be xanthin. Whatever they were, he found their presence in the blood varied with the uric acid in the urine. Their amount was reduced by salicylates. He believed uric acid was present in the blood.

Charles West died on Saturday, at the good old age of eighty-one years. As the founder of the Children's Hospital he has left a standing monument to his memory. He had been physician accoucheur and lecturer on midwifery at St. Bartholomew's Hospital, president of the Obstetrical Society, examiner at the university, and the recipient of many other expressions of the confidence of the profession. As a gynæcologist he long held a leading position, but I think that his work in pædiatrics will be longest remembered. It was no small thing to establish the first children's hospital and to carry it on to the great success it has attained. He was, further, the leading clinical teacher of the subject. His "Lectures on the Diseases of Infancy and Childhood" were first published in 1848, and has been a favorite text-book ever since. It reached a seventh edition in 1884, and each issue was kept abreast of the author's experience by careful revision. Of his other writings I may mention the Croonian lectures for 1854, which were entitled "An Inquiry into the Pathological Importance of Ulceration of the Os Uteri," and his Lumleian lectures for 1871, which he devoted to "Some Disorders of the Nervous System in Childhood." He delivered the Harveian oration in 1874. These lectureships show that he was appreciated at the College of Physicians, of which he became a fellow in 1848 and was censor from 1863 to 1870. He took M.D. at Berlin, 1837. Dr. West also published a volume of "Lectures on the Diseases of Women," which reached a fourth edition in 1879.

The title of honorary physician to the Queen has been conferred on Surgeon-Major-General C. A. McVettie, I.M.S., and Brigade-Surgeon-Lieutenant-Colonel Benjamin Franklin, C.I.E. Both have done good work in India. Their official designations illustrate the absurdity of the so-called compound titles.

TOXINS OF ERYSIPELAS AND CANCER.

To the Editor of the Medical Record.

Sir: My attention has been called to a circular recently issued by the Pasteur Vaccine Company, of Chicago, in which my name is used in connection with a preparation of the toxins of erysipelas and prodigiosus, which the above company has placed upon the market. The preparation is spoken of as a remedy for cancer; and it is furthermore stated that it is "especially adapted for use in the early stages of the disease."

I beg to say that my name has been used without my knowledge or consent, and for the benefit of those who are not familiar with my writings upon this subject I will add that I have never recommended the toxins of erysipelas except in inoperable cases, and practically only in inoperable sarcoma.

William B. Coley, M.D.

5 Park Avenue, New York, March 29, 1898.

THE VALUE OF THE CYSTOSCOPE IN THE DIAGNOSIS OF HYPERTROPHY OF THE PROSTATE GLAND—A FINAL WORD TO DR. E. FULLER.

To the Editor of the Medical Record.

Sir: Dr. Fuller, in his final word to me in your issue of April 2d, crystallizes his remarks around the definition of the word "configuration." He gives to understand that he had taken it merely in a plastic sense, whereas I have stated that I wanted to express with the same the condition of the prostate as we need to know it for our clinical purposes. This Nitze's cystoscope, No. 1, certainly can do. More I have never claimed for it, neither in my article wherein I first mentioned Dr. Fuller's name in connection with this subject, nor "elsewhere" in my answer to him.

It certainly is incorrect to make extravagant claims in behalf of the capabilities of the cystoscope. There are limitations to its usefulness, as every cystoscopist knows. They have been laid down in medical literature by many authors; five years ago by myself. On the other hand it is wrong, and the instrument is not helped with the profession by underestimating its value. For it has literally carried a bright light into the hitherto dark field of urinary surgery.

In his letter of March 6, 1898, Dr. Fuller says: "I do not in the least doubt that I or any one used to the cystoscope could see a median lobe of the prostate, provided it projected into the bladder almost as long as the third phalanx of the little finger." He continues: "In his case Dr. Meyer also states that there was besides general hypertrophy of the gland. He is, however, careful not to mention that he found that out by the aid of the cystoscope." Shortly before, we find in the same letter the statement: "In many cases of prostatic hypertrophy the obstruction is caused by growths about the prostatic urethra and about the vesical neck, regarding the presence of which the cystoscope does not give us the least information." These obstructing growths are the lateral lobes, the body of the prostate. They represent general hypertrophy of the gland. On March 26th, after quoting my words—"I meant, of course, that we can diagnose with the cystoscope whether the prostate is hypertrophied or not; if so, whether this hypertrophy is a pronounced or a slight one; whether there is a third lobe or not"—Dr. Fuller exclaims: "If that is all he means by configuration, then I am sure that I can see as much as he can."

It was of much interest to me, indeed, to see in how brief a space of time Dr. Fuller has come to recognize the value of the cystoscope in the diagnosis of prostatic hypertrophy, with reference not only to its median lobe but to the presence of obstructing growths about the prostatic urethra and about the vesical neck.

Willy Meyer, M.D.

New York, April 2, 1898.

THE MODIFIED O'DWYER TUBE.

To the Editor of the Medical Record.

Sir: In the Medical Record of March 12th, in the eulogy of the late lamented and talented O'Dwyer, by W. P. Northrup, M.D., the author unconsciously committed an error, the correction of which I suppose will always be in order. Speaking of the life work of O'Dwyer in intubation the author says: "The perfect intubation tube of to-day is made of hard rubber, and this latest improvement is from the hands of its inventor, Dr. O'Dwyer." This is certainly an error; for I have in my operating-bag a set of such tubes, and they are the invention of Dr. Louis Fischer, of your city. These tubes were presented in Philadelphia by the inventor during the meeting of the American Medical Association, June, 1897, before the section on diseases of children, and a description of them, with the cuts, etc., was presented in the Medical Record, June 19, 1897. In justice to the living as well as the dead, I thought this correction was in order. O'Dwyer's name and reputation are lasting and his life work will endure without the addition of the work of others; for the unselfish character of O'Dwyer is one of the proudest recollection of his friends and admirers.

Edwin Rosenthal, M.D.

Philadelphia, March 29, 1898.

PARACENTESIS OF THE DRUM MEMBRANE IN MIDDLE-EAR DISEASE.

To the Editor of the Medical Record.

Sir: The leading article in your journal of April 2d, "On the Treatment of Middle-Ear Disease," in which you dwell upon the plea of Dr. Woods, of Dublin, for the abandonment of paracentesis of the drum membrane as a routine practice, has interested me very much. I infer from your statements that it is a generally accepted belief among otologists, that paracentesis of the membrana tympani is actually such a proper procedure in acute otitis media, that its early performance has become a matter of routine with all good aural surgeons. This is certainly not true of the school of otologists to which I belong. I was very early in my warnings, in my text-book and in other places, that paracentesis in acute middle-ear disease was properly and safely undertaken only when there was a bulging membrane, and when the use of leeches and hot water had failed to give relief. The traumatism of a free paracentesis in an acute case is a very serious one, not to be lightly undertaken; as I have often said, an unnecessary paracentesis of an acutely inflamed membrane is a more serious procedure than the simple opening into the mastoid cells. By this statement and my other remarks upon this subject I still abide. I have never considered a paracentesis as a proper routine practice in acute disease of the middle ear. Now, if we add to the argument of the severity of the traumatism in this procedure in acute cases that of Dr. Woods, quoted in your editorial, as to the conversion of the tympanum into a

septic cavity by opening it, we may hope that the too frequent performance of what is mistakenly supposed in some quarters to be always a harmless procedure will cease. I have seen many instances where in my judgment an unnecessary paracentesis has greatly aggravated and prolonged the case, and one case in which I fear that death resulted as a direct sequence of the unwise procedure. Dr. Woods' opinion will not be so freely challenged, by Amerian otologists at least, as he has been led to suppose, although in his reasoning he in some respects differs from those of us who have long since deprecated paracentesis of the membrana tympani, as a routine practice in acute disease of the middle ear.

D. B. St. John Roosa, M.D.

April 2, 1898.

RED CROSS WORK IN CUBA.

[The following interesting letter to Dr. T. A. McNicholl, acting executive surgeon, Red Cross Hospital, New York, is published by the kind permission of the receiver.—Ed.]

Dear Doctor:—With all the work, I am absolutely unable to sit down and write. I have therefore requested one of the staff to write as I dictate. Red Cross work here is by the wholesale, so to speak, rather than by retail. The physicians who came from America—Dr. Hubbell and Dr. E. W. Egan, of Boston, and myself—have each their particular work, and are directed by Miss Barton

Dr. Hubbell goes into the field, investigates what food, medicines, and other things may be needed, then sends his report to the president of the Red Cross, who directs Dr. Egan to respond with such medicines and materials as the field agent may require. My own work is surgical and medical only. Together with other members of the medical profession of this city and county, I attend to almost everything of this kind, except diseases of the eye, ear, nose, and throat. Dr Egan, being a well-known specialist, has charge of that department, and performs his duty not only in a most capable manner but also with great alacrity. Knowledge gained in previous expeditions of this kind enables him to attend to a large number of patients in a very short time. You can imagine what his work is when between the hours of seven and eight he thoroughly examines, attends, and prescribes for from twenty to thirty patients.

My work here has been of a somewhat more difficult character than it would be under ordinary circumstances. Disease is far more serious during famine than at other times.

You can hardly realize nor is it possible for me to describe the misery existing in this country. Men, women, and children lie about the streets suffering from diseases of microbic origin or from starvation.

The hospitals are literally filled with the sick. On our arrival here we found a building of 108 x 40 feet, with two stories, each ten feet high, filled with patients lying on the floor one next to the other, each occupying just as much space as would barely permit him to turn around, while dirt and vermin covered the floors. So horrible was the picture presented that the president of the Red Cross, who has witnessed some of the greatest calamities of this century, shuddered at the sight. She immediately ordered us to have cots brought in and the patients placed on them, and the floors to be scrubbed and cleaned, so that the house to-day makes a fairly presentable hospital.

The people here have the idea that washing is injurious and permits a ready inoculation of disease, and I assure you it is often very difficult to convince them of the contrary. So far does this belief go that an argument has been made to the effect that wild animals have no means of washing themselves with soap. However, those in our charge are thoroughly cleaned and are doing very well.

Other hospitals here have not the same disadvantages, as they are well cared for by the Sisters of Charity, who, while not attending to the work of orderlies, do take charge of the nursing.

The sick of this island have one great advantage in this, that the medical profession is composed of highly educated physicians and surgeons, who need no physiological or pathological demonstrations for the purpose of explaining a certain disease or system of therapeutics. The brotherhood is far more closely united than in many other countries.

The diseases from which most people suffer now are malarial fever and gastro-entero-colitis. The former seems to be more severe than at any time previous. The latter is due entirely to famine; perhaps not so much to starvation as to improper food. No special bacillus has been found, although it appears that the disease has a regular course. No doubt malarial diseases complicate these conditions to such an extent that one hardly knows at what moment a new symptom may not develop. The symptoms or conditions have no regular term of duration, but usually succeed each other as follows: first a chill, during which the temperature goes up to 103° and 104° F. (39° to 40° C.); then come headache, nausea, sometimes vomiting; then diarrhœa sets in; then very marked tympanites resembling a typhoid condition. Usually there is no pain, except on pressure. If malarial fever accompanies the disease—that is, if the plasmodium is found in the blood—these conditions usually come in paroxysms either every morning or every evening. The tongue seems clean, in fact destitute of epithelium, but the complaint of a burning feeling in the œsophagus and through the alimentary tract is usually made by the patient.

Apparently with regular diet and very little medicine, if malarial complications are absent, the disease diminishes in severity until the patient recovers from all symptoms except marked tympanites. The anæmia which develops during this difficulty is so profound that not only is the number of corpuscles diminished, but the specific gravity of the blood is far lower than can be accounted for by the absence of the globular elements. The liver enlarges, although other symptoms have improved and although no plasmodium is found. Suddenly the patient begins to suffer from general anasarca. The hydrops is so extensive that one is reminded of the condition which is exhibited when a bag is inflated; again, the bowel difficulty sets in and the patient dies of intestinal hemorrhage.

The autopsies have shown nothing but what usually would be found in septic diseases. It would require too much space for me to mention the conditions in which the various organs are found.

Malarial fever may complicate, as stated, or may affect the patient without the intestinal symptoms—simply a chill, fever, and sweating-stage—and frequently it does not yield to the use of quinine, although the plasmodium is found.

I have introduced a new system of treating malarial fever with sulphur and camphor; I sometimes add a little capsicum when no intestinal disease is present.

The proportions are:

R Sulphur	1 gm.	(gr. 15).
Camphor	0.1 gm.	(gr. 1½).
Capsicum	0.01 gm.	(gr. ⅙).

This dose is given three times a day. The success has been so marked that last Sunday a report of this treatment was made at the academy, for which purpose I was officially invited. Next Sunday the

clinical associations have a meeting, to which also I have been invited.

The treatment seems to give universal satisfaction and, as proven here, is productive of far better results than quinine.

The facilities of the laboratories and universities are placed at my disposal. My invitations to the various hospitals, together with the work at the Red Cross Clinic and Orphanage, which latter now has on the average one hundred inmates, keep me very busy.

My investigations into the diseases consequent upon famine I hope will be pretty complete, owing to many advantages offered me by the medical profession in this city.

It would be improper for me to say more, at this time, except that alcohol in every form has been discarded here during the progress of fevers.

A. Monae Lesser, M.D.,
Executive Surgeon, Red Cross Hospital, New York.

Havana, March 19, 1898.

Surgical Suggestions.

New Antiseptics.—According to the experience and experiments of Le Dentu (Paris) formol and parachlorphenol should be added to the list of classical antiseptics (carbolic acid, bichloride, chloride of zinc, iodoform, salol). The sterilizing power of formol is twice that of bichloride, while its deodorizing power is very marked. In a 5 to 1,000 solution formol sterilizes instruments without any injurious effects. Parachlorphenol is five times as strong as carbolic, and attacks instruments but slightly. Its absorption gives rise to dark urine (surgical section at the Moscow Congress).

Technique of Subcutaneous Symphyseotomy.—Secure full dilatation of the cervix, if possible without risk to the child. Have the urethra and bladder held to one side with a sound. Make the initial incision a little above the subpubic arch and under the elevated clitoris. Introduce the left index finger within the vagina against the posterior groove or ridge of the joint, up to the top. Pass a narrow tenotomy knife with the point close to the joint, up to within a half-inch of the top and under the overlying soft tissues. Substitute a probe-pointed bistoury and meet the left index finger with the probe over the top of the joint and work the blade through the joint downward, until separation is felt by the posterior finger. Have an assistant press the mouth of the wound and the tissues lying over the joint with a small piece of gauze. Deliver with forceps, if possible, and refrain from suprapubic pressure, aiming to deliver the head through the cervix without drawing the latter down below the symphysis. Hold the bladder well to one side while pressing the pubic bones together. Pass a small strip of gauze into the prepubic wound and another against the cervix after irrigating, leaving both pieces exposed for easy removal, having refrained from stitching cervix or perineum. Introduce a soft-rubber retention catheter into the bladder, and leave it until sure the patient can voluntarily micturate. Dress the vulva with gauze and strap the joint with adhesive strips. Remove all the gauze in thirty-six hours and irrigate vulva and vagina twice a day, keeping the vulva carefully dressed between times.—Ayers.

Serum Therapeutics in Tetanus.—When tetanus has once declared itself, the antitoxic serum has no action; it is powerless to arrest the fatal termination of the disease, and this without reference to dosage or strength of serum; those alone are cured who would have recovered in any case. The serum treatment is, however, useful even in actual tetanus, for although the number of cures is not increased, yet those who do recover do so more quickly. The antitoxic serum, even in weak dosage, if employed at the moment of the reception of the suspicious injury, or even some time afterward, will prevent the onset of the disease. The dose must be both larger and stronger according to the length of time intervening between the reception of the wound and the employment of the serum; intravenous injections are more potent than hypodermic; the attack of tetanus is not always warded off, but, as a rule, if the disease occurs it is of a mild type, and the animal recovers, even though injected with a dose of toxin invariably fatal to a control animal.—Edward Nocard.

Vasectomy, or Division of the Vasa Deferentia, for Some Forms of Vesical Fistulæ Associated with a Large Prostate.—The simplest method for resecting the vas appears to consist in exposing the spermatic cord as it joins the scrotum, by a linear incision over it about an inch in length. The vas is readily made out and protruded toward the incision by pressure from behind, between the finger and thumb. It can then be easily seized with a pair of Spencer Wells' clamp forceps and brought to the surface, where it is cleaned by a little dissection, and a blunt hook or aneurism needle passed beneath it. A loop is included by a silk ligature and the free portion removed by scissors. To ligate the duct is insufficient, it being necessary to resect a portion of it. After the loop has thus been removed the stump is returned with the ligature cut short, and the little wound is then closed with a suture or two. Union usually takes place in the course of a few days. In this way the operation can be performed quickly and almost bloodlessly.—Reginald Harrison.

Treatment of Fractures.—Reclus says: "Immobilize the fragments, but mobilize the muscles, tendons, and joints. Massage will improve the circulation, lessen the pain, tend to prevent adhesion of the tendons to their sheaths, promote the absorption of inflammatory material, and prevent contraction or atrophy of the muscles. Passive motion judiciously employed tends to prevent the limitation of the motion of joints by the formation of strong fibrous bands, and likewise to replace any displaced fragments of bone and keep the part in its normal shape. The importance of union and avoidance of deformity is so great that it is, as a rule, unwise to resort to massage or any marked movements until the fragments become to a certain degree fixed in the proper position, usually from the sixth to the tenth day, and in the lower extremity frequently much longer. Afterward, the more frequent the movement and massage, if effected gently and without disturbance of the bones, the quicker the recovery. Daily massage will not be too often."—*Annals of Surgery*, December, 1896, p. 691.

Dressing after Circumcision.—Lead water and laudanum are a better dressing for the first two days after circumcision than all the antiseptics combined. They not only prevent swelling and œdema of the penis, but the opium prevents erection, which so frequently occurs in these cases.—Horwitz.

Treatment of Rupture of the Posterior Urethra.—1. With moderate hemorrhage from the urethra, little or no perineal swelling, and without any trouble in passing urine, very little treatment is necessary. 2. If there be difficulty in micturition, and the other above symptoms are mild, then a temporary catheter should be introduced. 3. If catheterization fails, or if the symptoms are grave at the outset, then an im-

mediate operation is necessary and the torn urethral ends ought to be brought together by suture.—K. S. Lɪᴀᴍᴀɴᴅʀᴇ, *Archiv fur klinische Chirurgie*, xliv., S. 479.

Examination of the Shoulder for Injury.—In examining the shoulder for injuries, the following method of procedure should be employed: Stand behind the patient and examine the two shoulders consecutively—one with each hand. Starting at the interclavicular notch, pass the fingers out along the clavicle to the acromial process, and then draw the hands backward along the spine of the scapula. Now have the patient put his hands high against his back, and follow down the inner edge of the scapula and around its angle, which will be prominent. Next grasp the shoulder, placing the thumb on the acromial process and the finger on the coracoid. The head of the humerus should be between them. Place the finger in the axilla with the thumb on the acromion and have the arm moved in different directions.—Bʀɪɴᴛᴏɴ, *Dunglison's College and Clinical Record.*

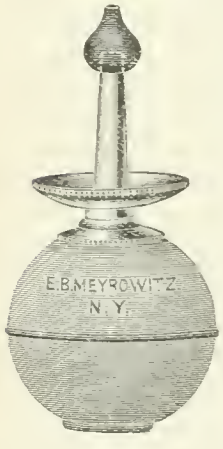
New Instruments.

A NEW ASEPTIC EAR SYRINGE.

By FRANK ALLPORT, M.D.,

CHICAGO, ILL.

A piston syringe of whatever variety is invariably septic, and therefore unfit for use. Let any aurist take apart his nickel-plated ear syringe and smell of and observe the piston and its packing, and bacteriological examinations will be unnecessary to convince him as to its unfitness for use in aural or any other work. I have therefore made use of the old bulb idea in devising a new ear syringe, as seen in the accompanying illustration. The bulb is as large as can be conveniently used by the hand, and contains between two and three ounces of fluid. It is firmly connected with a projecting nickel-plated tube, and does not leak. A shield is attached to the tube, near the bulb, as a protection to the operator and clothes of the patient. This can be unscrewed and removed if desired. The projecting tube tapers down to a rounded and smoothed end, which is of the proper size for an ordinary meatus. An olive-pointed tip accompanies the syringe, which can be slipped (not screwed) on the end of the tube, if desired. The force of water with this syringe is as strong as should ever be used in an ear.



As only antiseptic or aseptic solutions should be used in an ear syringe, and as the foul piston is eliminated from this one, there is no reason why the interior of this instrument should not always be pure: if not, it can easily be purified by allowing a strong antiseptic solution to pass into and remain in the bulb, and in fact it could always be left soaking in such a solution if desired. The bulbs can be easily replaced when worn out, if desired. I believe this syringe will be a safe and useful one to place in the hands of patients, when for any reason we desire them to use one at home.

The syringe has been manufactured for me by E. B. Meyrowitz, of New York.

92 State Street.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending April 2, 1898:

	Cases.	Deaths.
Tuberculosis	222	120
Typhoid fever	16	5
Scarlet fever	151	25
Measles	451	2
Diphtheria	176	25
Laryngeal diphtheria (croup)	9	6
Chicken pox	30	0
Cerebro-spinal meningitis	1	0
Pertussis	5	0
Erysipelas	1	0
Parotiditis	3	0

The Tsarina has Small-Pox.—The Tsarina is down with small-pox. Many another has been, too. The Saracens found the disease in Africa, and introduced it into Europe. That was twelve hundred years ago. Until Jenner came it was fashionable among all classes. Said Louis XIV. of France: "I have the small-pox." A courtier answered: "Sire, so has every one." He was not sympathetic merely; he was exact. It heightened Queen Elizabeth's absence of beauty. William III. gave it to one of his pages, and that the honor might be becomingly remembered gave him the duchy of Portland also. Maria Theresa had it. So did Queen Mary. It was endemic in palaces, but it was not confined to thrones. When it reached this part of the world, it singularly aided the civilizing influence of Spain. Out of Mexico alone it took nearly four million people. In South America its helpfulness was relatively as great. Then, returning to Europe, it depopulated the Northland. A century ago Jenner got to work at it; thereafter its efficiency waned. The Tsarina is the first modern sovereign whom it has attacked.—*Collier's Weekly.*

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended April 2, 1898:

Small-Pox—United States.

		Cases.	Deaths.
Arkansas, Little Rock	March 31st	2	
Florida, Jacksonville	March 10th to 26th	1	
South Carolina, Arkwright	March 25th	9	
Dyson	March 25th	3	
Pelham	March 25th	20	
Ridge Springs	March 25th	1	
West Virginia, Bluefield	February 28th	5	

Small-Pox—Foreign.

Bohemia, Prague	February 26th to March 5th	8	
Brazil, Rio de Janeiro	January 8th to February 18th	11	1
Cuba, Cardenas	March 5th to 12th	..	1
Cienfuegos	March 13th to 20th	..	3
Havana	March 10th to 24th	24	15
Regla	March 10th to 24th	..	24
Sagua la Grande	March 5th to 19th	137	3
Germany, Hamburg	March 5th to 12th	2	
India, Bombay	February 15th to 22d	..	1
Calcutta	February 5th to 19th	..	6
Madras	February 12th to 28th	..	7

ON THE OPERATION OF GASTRO-ENTEROSTOMY CONJOINED WITH ENTERO-ANASTOMOSIS.[1]

By ROBERT F. WEIR, M.D.,

PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; SURGEON TO THE NEW YORK HOSPITAL, ETC.

Not long since, in alluding to the operation of gastro-enterostomy as applicable to certain forms of ulceration of the stomach and of spasm of the pylorus, I felt justified in stating[2] that this operation was yet, in its technique, in an unsatisfactory condition. I venture, therefore, in presenting this evening a specimen illustrating this operation, performed by the method known as that of Jaboulay and Braun—in which not only is gastro-enterostomy done, but also an entero-enterostomy—to ask a few moments' attention to the various points that have of late years attracted surgical notice. The history of the case is as follows:

Cancer of the Pylorus; Gastro-Enterostomy, Entero-Anastomosis with Murphy Buttons; Death on the Third Day from Bronchitis and Pulmonary Œdema.—Arthur E——, aged thirty-five years, was referred to me by Dr. Kortright, of Brooklyn. For more than a year previous the patient began to feel that he was losing his health, and for nearly a year he had been troubled with severe indigestion without vomiting, but accompanied by eructations of gas and occasionally of sour fluid. Loss of weight (one hundred and thirty pounds instead of one hundred and sixty) and strength had been more noticeable in the last six months, and his color had become bad. The appetite continued good and there was little pain, but there was obstinate constipation and the feebleness progressed. At the time I first saw the patient, February 23, 1898, there was a well-marked tumor in the epigastric region, the size of an egg, hard, and freely movable. This had first been made out some eight months previous. With this history and by physical examination the diagnosis of carcinoma of the pylorus was not difficult to establish, and it was advised that an attempt be made to build the patient's strength up a little before subjecting him to the strain of an anastomosis. After two weeks' delay with systematic and repeated feeding, by which his condition somewhat improved, an operation was performed as follows: A short median incision was made. The stomach and intestines were found nearly empty and the pylorus was examined; it was, as expected, carcinomatous but without adhesions. The omentum and transverse colon were now lifted out through the wound and an opening was torn through the mesentery of the latter with the fingers. The posterior wall of the stomach was then drawn through this opening far enough to permit an anastomosis being easily made by means of a Murphy button, medium size, between it and a loop of the jejunum some twenty inches from the duodenum. The half of the button which was placed in the jejunum had a special flange, projecting one-eighth of an inch from two sides and well rounded off, to prevent its falling back into the stomach: and instead of the usual puckering-string being used the ends of the very short incision, made to allow the forced insertion of the button into the gut, were brought together by a couple of stitches. This allowed the two halves of the button to be brought closer together, with the walls of stomach and intestine smoothed out between them. Four Lembert stitches of black silk were inserted around the closed button as an extra precaution. The ascending and descending limbs of the loop of jejunum were then anastomosed with the next smaller-sized button in the same way, except that no Lembert stitches were used. The operation, from the opening to the closing of the peritoneum, occupied but twenty-two minutes, and almost no blood was lost. The patient took a minimal amount of ether, less than three ounces, and left the table in good condition. At the end of the second day he developed a bronchitis which interfered with his breathing and weakened him by spells of coughing. This continuing on the fourth day, œdema of the lungs developed and death ensued. Up to that time the patient had had no abdominal symptom, and he had taken nourishment from the twentieth hour after the operation and retained later two ounces of fluid, beef broth, or peptonized milk every hour, without vomiting or any gastric disturbance. He also had rectal feeding. How well the stomach was acting was shown by the fact that not a drop of fluid was found in it when it was opened at the autopsy. There was nowhere any adhesion, or redness, or any distention of any portion of stomach or intestine. The whole posterior portion of both lungs was much congested and filled with fluid, and the usual signs of bronchitis were present. The specimen is presented for inspection.

The establishment of a new route between the stomach and the jejunum is not only, as is well known, employed for the relief of benign and malignant obstructions at the pylorus, but also for the relief and cure of other and often more obscure gastric affections, such as painful or hemorrhagic ulcerations and their sequelæ of adhesions, etc.; as well as for those troubles, likewise painful and often spasmodic, which are supposed to be due either to hyperacidity *per se* or to unduly augmented gastric secretions, the so-called disease of Reichmann. These latter affections, rarer here than in Europe, have only lately been subjected to surgical treatment, but so far with a very brilliant success.

The first employment of a gastro-enterostomy opening was made by Wolfler, in 1881, for inoperable pyloric carcinoma, and consisted in the attachment (Fig. 1) of the jejunum, as near as convenient to the duodenum, to the anterior wall of the stomach. This necessitated that the omentum, often quite large, should be drawn up behind the loop of the small intestine, which not only compressed the colon somewhat, but, what was of more importance, dragged thus directly or indirectly upon the small intestine, now fastened to the stomach. This traction was apt to cause the intestine on

[1] Read at a meeting of the surgical section of the New York Academy of Medicine, March 14, 1898.

[2] "The Surgical Treatment of Round Ulcer of the Stomach and its Sequelæ," by Weir and Foote, Medical News, April 25, 1896.

one or both sides of the opening to make so sharp a bend that three things frequently occurred: either the contents of the stomach would not pass out freely enough, or, what was more important, the bile entering the duodenum would not flow along the free edge of the intestine beyond the gastro-enteric attachment, but it would enter the stomach, remain there, and produce exhausting vomiting; or, a complication which was but a variety of the second one would take place—that is to say, the bile would not either enter the stomach or pass by the projecting spur formed opposite the gastro-enteric opening (see Fig. 2).

To obviate these difficulties, which became at once apparent—for the operation was widely practised, particularly at first for inoperable carcinoma and subsequently for the other lesions already noted above—Wölfler, to confine the description for the time to this one surgeon's efforts to improve the technique, tried, in order to overcome this faulty egress from the stomach, the manœuvre suggested by Lücke, so to arrange the intestine that the stomach should discharge if possible into the efferent or descending branch of the jejunum, and hence to accomplish this the intestine was

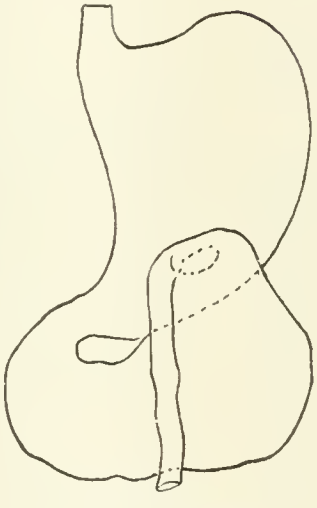

Fig. 2.—Obstructive Bile Dilatation of Duodenum and Jejunum.

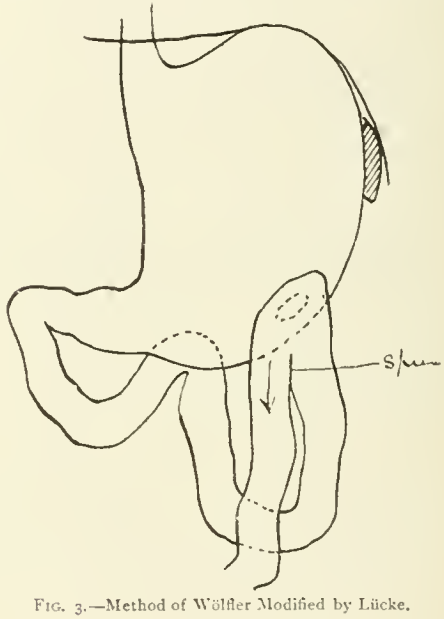

Fig. 3.—Method of Wölfler Modified by Lücke.

distentions of the stomach, etc., are so many that a constant good position cannot be counted on.

This fixation of the small intestine for a considerable distance on each side of the gastro-enterostomy opening has been followed by operators in most of the recently performed anterior operations, and with some diminution of the obstructive risks. Some, like Doyen (Fig. 6), consider it important that such suturing should run in a specific direction, that is to say, from above downward and to the right, in order to facilitate the passing onward of the bile and stomach secretions. Others have endeavored to make directing flaps, either in the intestinal wall itself, in forming the gastro-enterostomy opening, like Kocher[1] (Fig. 7) and Chaput[2] (Fig. 8), or by dimpling the jejunum just before it reaches this opening, so as to divert the stream of bile away from the stomach and along the free wall of the intestine. This, again, is a suggestion of the prolific French surgeon, Doyen (see Fig. 9), who does even more than all this to perfect this operation; for, in addition to suturing the jejunum widely to the stomach and making a directing flap, he also fixes to this same viscus the colon (Fig. 10), and for the reason given a reversed loop on itself and attached to the stomach, and thus the contents of the viscus could now flow onward in the correct or normal direction (Fig. 3). Kocher subsequently insisted that this turn or twist of the intestine should run from behind forward rather than from left to right, which latter Lücke had proposed, and which has been until recently generally adopted. Wölfler and also Roux have finally proposed, in order to obviate the foregoing complications, to cut across the jejunum and to fix (Fig. 4) its distal end into the stomach and its proximal divided end into the distal jejunum a short distance below its gastric attachment. Others as well as Wölfler have endeavored to avoid these spurs and kinkings by suturing considerable portions of the jejunum on one or both sides of the gastro-enteric opening. It is true that by this manœuvre the stomach was dragged from its vertical position, but it was hoped that dependent gut might hang advantageously at the angle, so neatly shown in Fig. 5. But, the fatal but, is that no one can count on what position a coil or portion of intestine will remain in after its replacement in the abdominal cavity, even when sutured to the stomach over a considerable length. The changes from peristalsis and from gravity action, from adhesions, and from varying already alluded to, that when the loop of intestine is drawn up to the stomach it of necessity pulls up and has to bear the weight, first, of the crumpled-up omentum and also of the then crowded-down or loaded transverse colon. Hence Doyen, to do away with the first difficulty, with much ingenuity tears a hole through the gastro-colic fold and pokes through this into the cavity of the lesser omentum (that is to say, behind the stomach) the omentum majus, and then, as just stated, stitches the colon to the stomach. What future influence this dislocated and possibly increasing mass of fat may subsequently have on the adjacent viscera time must show, but the method is yet too new to do other than speculate about it. Doyen's success in this operation, in spite of its duration (forty or sixty minutes) has been far beyond that of his compeers. He gives eighteen operations without a single death, but of these in fifteen cases gastro-enterostomy was performed for supposed ulcers and gastralgias from hyperacidity or gastric succorrhœa (Reichmann's disease), conditions certainly not so serious even as the ordinary benign pyloric stenosis, of which he had three cases, also all successful, though with eight cases of

[1] Kocher: "Chirurg. Operationslehre," 1897, p. 172.
[2] Chaput: La Presse Médicale, July 14, 1894.

malignant pyloric disease his mortality reached 37.5 per cent.

It is perhaps advisable to interrupt here this quasi-chronological *résumé* of the endeavors to secure a proper delivery of the bile and stomach contents to the intestine below the artificial stomach opening, in order to speak more definitely concerning the frequency of these obstructive difficulties; for enough has been shown, I think, to prove that the dragging from the stomach of the fastened intestine is likely in any case to occur, whether this attachment be limited to its minimum, as it is when a Murphy button is used, or whether it be extended widely by additional suturing. At its free portions above or below, or at both points, there can occur in all these methods where the opening is made in the anterior gastric wall, such sharp kinking from extrinsic and intrinsic causes that spurs and obstruction may and are likely to take place. The possible exception to this statement may, however, be the long and complicated operation of Doyen, but it requires the confirmation of other surgeons.

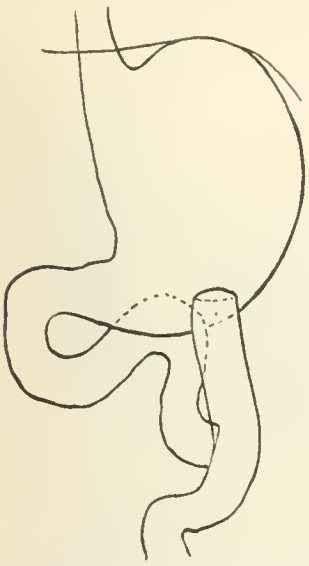

FIG. 4.—A Modification by Roux and by Wölfler of a Gastro-enterostomy with Entero-anastomosis. (Compare this with Fig. 12.)

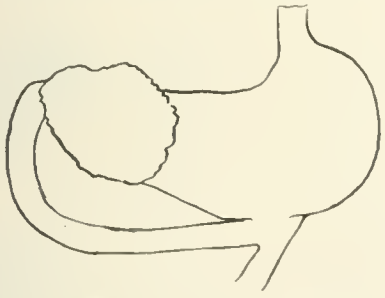

FIG. 5.—Wölfler's Method, 1896 (Schematic).

From Chlumskij's[1] and from Carle and Fantino's[2] recent excellent articles (from both of which many of the statistics and illustrations have been obtained) I find that Carle had in twenty cases of anterior gastro-enterostomy five deaths, and in every one of these at the autopsy it was seen that the afferent or ascending loop of the intestine was distended with bile and that a large quantity of the same fluid had collected in the stomach, while the efferent or descending intestine was empty. Chaput[3] also reports four deaths in seven cases from bile obstruction, with uncontrollable vomiting. Mikulicz in seventy-four cases had with his extended experience eight cases of this obstruction, six of which were due to a kinking of the anastomosing loop, one to the formation of a spur, and one to the compression exercised by the colon. My own cases are limited to seven—four[4] benign, three malignant. Three out of the four benign cases were operated on anteriorly by Abbe's plates; in the fourth I used Kocher's flap method. Two of these patients recovered, two died: one of hemorrhage from the gastric wound (my own fault) and the second operated on by Kocher's method of bile obstruction and vomiting. Of the three malignant cases, in two I made the gastro-enterostomy anteriorly by triple silk suturing.

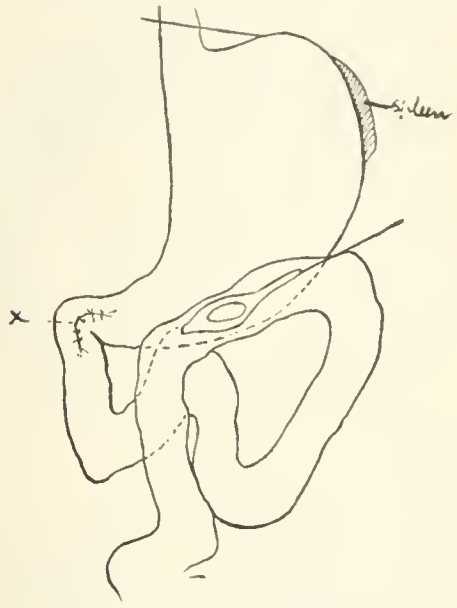

FIG. 6.—Doyen's Method of Anterior Gastro-enterostomy. *x*, Coincident narrowing of pylorus in certain cases.

One of these patients recovered; the second died of bile obstruction; in the third case, the history of which I present to-night, death came from an ether bronchitis, which is not uncommon in weak patients, but the operative field was undisturbed by any mishap whatever. And this I consider sustains the point that I have been thus slowly leading up to, for here, besides resorting to the creation of an opening between the stomach and the intestine, I also employed the suggestion first made, though in an imperfect shape, by Lauenstein in 1890 and improved by Jaboulay and Braun[1] (Figs. 11 and 12), of making a separate opening between the afferent and efferent

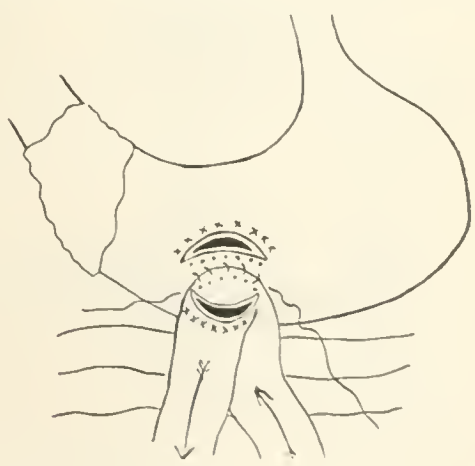

FIG. 7.—Kocher's Flap Method of Gastro-enterostomy with postero-anterior attachment of jejunum.

loops of the attached jejunum. In this case of mine, however, Murphy buttons were used, the medium size for the stomach opening and the smallest size for the entero-enterostomy. This latter was intended as a

[4] Since this was written I can report another successful case of my own, done with a medium-sized modified Murphy button—inserted in the posterior wall of the stomach by v. Hacker's method. Safety sutures used—no entero-enterostomy.

[1] Braun (1892) and Jaboulay (1892): Centralblatt für Chirurgie, 1892, S. 102; Archives Provinciales de Chirurgie, pp. 1–19.

safety valve should obstruction occur, but in the present case not the slightest evidence of obstruction was met with. The patient's condition was not very good, but under the exhaustion developed by his bronchitis it was advisable to give nourishment, etc., as early as twenty hours after the operation rather than further to rely on rectal alimentation only. As the diagram shows, Lauenstein originally proposed tapping an adjacent loop of small intestine, but Jaboulay and Braun nearly at the same time used the two legs of the intestinal loop for the second anastomosis. This method has been long enough before the public to have had its merits fairly tested. Mikulicz in eight cases in which bilious vomiting was marked, thus showing outgoing

obstruction, reopened the wound and did an entero-anastomosis, saving four of his patients. He advises its use when gastric atony exists or is suspected. In one of my own cases I also did a subsequent entero-anastomosis, but failed to obtain relief. Chaput, already quoted, says of this procedure that it is in-

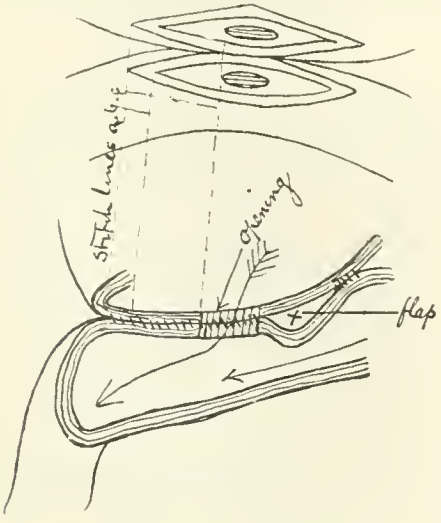

Fig. 9.—Doyen's Method, Showing Lines of Sutures, and also formation of directing flap by dimpling at *x* the afferent jejunum.

dispensable, according to his judgment, to practise systematically this additional entero-anastomosis to ward off the mishaps of spurs and kinks. He also had used the method successfully to relieve a progressing obstruction after an ordinary gastro-enterostomy. Other

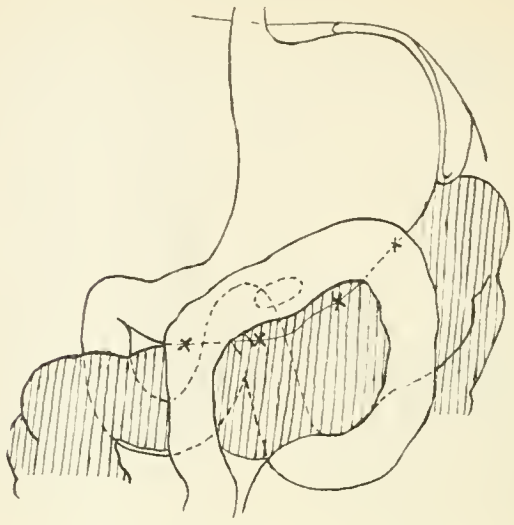

Fig. 10.—Doyen's Method Completed. *x* = Final suturing of colon to stomach.

suggestions have been added to this one. Chaput (Fig. 8) stenoses by a ligature the afferent jejunum to force the bile flow through the entero-anastomosis—a proceeding unnecessary in my judgment, and a similar criticism applies to Doyen's plan (Fig. 6) of narrowing the pylorus to prevent regurgitation by the opening into the stomach. To do away with many of the risks of the anterior gastric opening, v. Häcker in 1886 suggested that the jejunum should be attached to the posterior wall of the stomach, and claimed for this posterior gastro-enterostomy in 1892 that experience showed that it did away with the causes that produced bilious and pancreatic obstruction, but Doyen, who advocates the anterior operation with his modifications, while admitting this, says that the increased risk of the posterior opening sets off its freedom from obstruction. Chlumpskij has also found that the posterior gastro-enterostomy in one hundred and fifty-two cases was followed fourteen times by bilious vomiting which resulted fatally in eight of these instances.

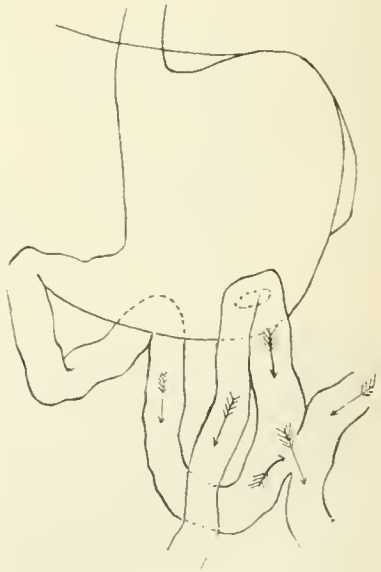

Fig. 11.—Method of Lauenstein.

As to the difficulty of the v. Häcker operation it is only encountered in the comparatively few cases in which it is impossible to draw the stomach through the opening in the mesentery, and as to the comparative risk of the two operations of Wölfler (anterior) and v. Häcker (posterior) the statistics which I shall later present show but little difference. All this indicates that although posterior gastro-enterostomy is more exempt from obstructive incidents, it is not yet an ideal operation.

The time that you allot me is too short and my descriptions are already too long to permit me to dwell much on other interesting points concerning this operation, but the few moments left me can be spent in a brief consideration of the utility of Murphy buttons, either in a simple gastro-enterostomy or with it an associated entero-anastomosis. This mechanical device has steadily advanced in surgical esteem, and time and experience have dissipated many of the objections urged against it. It has, for instance, not brought about, as far as I know, except in one doubtful case,[1] any obstruction in its eliminative passage downwards into the lower bowel. It has not been at all superseded by any of the potato, bone, or other temporary contrivances of Dawbarn, Robson, and others. It has only encountered the objection that, owing to the greater thickness and therefore the slower separation of the stomach slough, the button frequently passes into and remains lodged in the stomach.[2] It apparently does little harm there, and I have seen it *in situ* by means of an *x*-ray photograph. This is a reliable means of recognizing the final destination of a lost button, and I doubt not that before long some enterprising surgeon will give us views of the button *in situ*, *en route*, and on arrival in the rectum. Twice I have endeavored to guard against such an accident—once by attaching to the lower end of the Murphy button a string some five or six inches long, at the end of which I fastened a shoe button. This was done with the idea that the peristaltic action of the intestine below would sufficiently pull on my string and its improvised sinker to coax the button downward along the intestine. My second endeavor was used in the present case. It consisted in having the intestinal portion of the Murphy button elongated one-eighth of an inch on two sides, so that it presented an oval appearance (Fig. 13), the oval parts being formed by the projecting ledge. As both cases terminated fatally, nothing was proved for my devices.

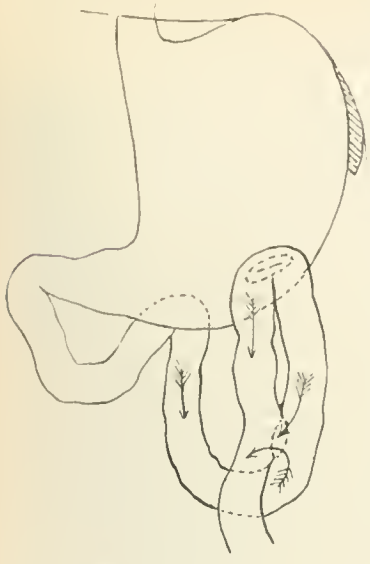

Fig. 12.—Method of Jaboulay and Braun.

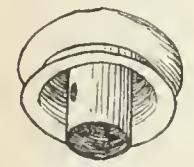

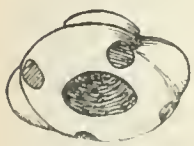

Fig. 13.—A Murphy Button modified by oval elongation of its intestinal half to prevent its slipping into the stomach.

The buttons, both in the stomach and in the intestinal loop below, were in the present case inserted after Carle's method, which is a variation from Murphy's original procedure. It requires, I think, less time, and brings the intervening portion of the intestine or stomach more smoothly about the central cylinders or standards of the buttons. Carle uses no "purse-string" suture, as advised by Murhpy, since this often throws up unwieldy folds, particularly of the stomach wall, and demands extra safety sutures; but he makes at once a quite small opening, first into the intestine, and forces the half of the button through it into the bowel, and immediately closes any part not fitting closely to the cylinder with one or two silk sutures. This leaves the peritoneal surface smooth and uninjured at the peripheral point of contact of the other portion of the button. The stomach is similarly treated and the two halves of the buttons are confronted and pressed together, as is customary. Nevertheless, in spite of Murphy's reiteration that safety sutures are unnecessary, he, like many others, prefers to employ an additional row of sutures about the button for safety, and Chaput has collected eight cases of gastrostomy and sixteen of enterostomy in which separation of the button occurred before good peritoneal union had taken place. Therefore in only those cases in which extra haste is demanded is it considered advisable to rely on the button apposition alone. Czerny, however, whose experience is large, advises with others against using safety sutures.

Fig. 14. Posterior Gastro-enterostomy by v. Hacker's Method, showing the opening made through the mesentery.

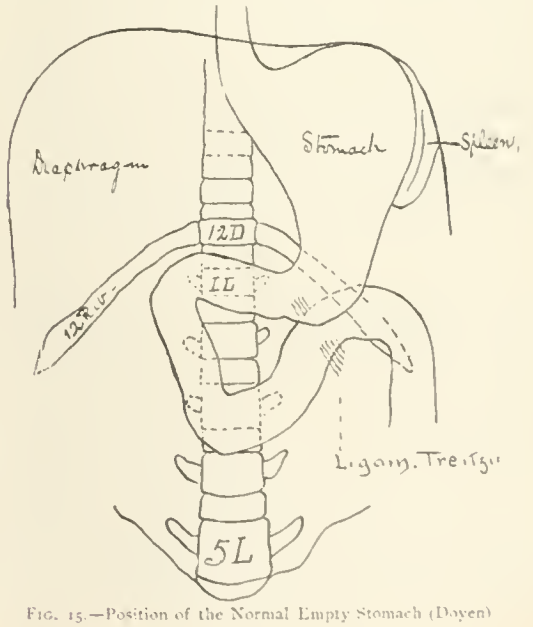

Fig. 15.—Position of the Normal Empty Stomach (Doyen)

[1] Dagros quoted by Chaput, Semaine Médicale, p. 534, 1894, who says that in the dead body a Murphy button twenty-seven millimetres in diameter will not pass along the small intestine, but he does not allow for the elasticity of the intestine in the living subject.

[2] Carle states that in thirty-two instances when the button was used it was found in the fæces only nine times and in four cases it was found in the stomach. Czerny, in thirty-five gastro-enterostomies, however, reports that in his cases the button in no instance passed into the stomach.

The better results that come from the use of the Murphy button are not only from the diminished time required (twenty to twenty-five minutes and often less, and in my own case only twenty-two minutes were required for the insertion of both the buttons from the opening to the closing of the peritoneum), but also from the broader support given by the button to the pendent intestine, for I feel sure that during the brief use of the plates and rings of Senn, Abbe, and others, there was less of the complication of bile obstruction encountered than was afterward noticed—a difficulty that, as previously stated, has been only partially done away with by the extended suturing of the bowel to the stomach. It is encouraging, too, to note how seldom are reported, though they do occur, the contraction and obliteration of the round opening made by the button. With the linear incision into the stomach of even two or two and one-half inches long, recontraction to a dangerous degree, or even to completeness, took place not infrequently.

A few sentences to touch on the points as to the location of the opening into the stomach and the method of most quickly finding the jejunum will, with a *résumé* as to the results obtained by experts in this operation, close my remarks. The anterior operation (Wölfler's), while easier, is as previously shown, yet associated with the dragging effects of the omentum and colon, unless the complicated measures of Doyen are adopted, and also has the disadvantage that may come from any distention of the stomach whereby not only is the opening raised to a higher level and unduly twisted, but more tension is likewise thus made on the attached intestine.

Hence more frequently is the posterior opening (v. Häcker's) advised by surgeons.[1] Here by a median cut the stomach is exposed and examined if necessary; the omentum and transverse colon are then drawn out from the wounds. The mesocolon is now torn or cut through to reach the posterior wall of the stomach over an area some two inches in diameter (Fig. 14); through this the stomach is drawn out beyond the wound. One can now, if it is wished, shut off the cavity of the lesser peritoneum which has thus been opened into, by stitching the torn edge of the mesentery to the stomach (Brenner), or this can be disregarded. The jejunum is now sought for; the stomach, omentum, and colon being duly covered with warm, dry (preferred) or moist sterile gauze are gently held by an assistant. To reach this intestine quickly the plan of Socin I have found the most satisfactory. It is this—to pull moderately on the colon after this with the omentum has been drawn out of the wound; this stretches its mesentery a little, and near its base you will find, either over the vertebra or to its left, the intestine. Traction upon this will show its duodenal fixation, and then some thirty to sixty centimetres of this bowel is brought out to be attached, as above directed by Lücke, to the posterior wall of the stomach, eight or ten centimetres from the pylorus. The reason for the choice of this locality in the stomach will be evident on glancing at Fig. 15, which Doyen,[2] and before him Glénard, has given as the proper position of the stomach when one is in the erect position. This, however, I am inclined to doubt a little, as the line in stomach exploration by distention with gas and fluid is in a similar position more oblique; but the gastro-enterostomy opening should be fairly low down, and tolerably near the pylorus if practicable. This permits ready egress of fluids from the stomach in both the erect and the recumbent positions. The posterior operation is not materially a more difficult one than the anterior, and it eliminates at once to a decided degree the evils belonging to the anterior operation. There only remains the traction, slight in itself, of the caught-up intestinal loop. It is even possible here, however, to suture the bowel along the stomach, if it is desired.

Concerning the results—that is to say, the mortality following a gastro-enterostomy—the following figures taken from Chlumskij will be of interest:

From 1881 to 1885, 35 operations were collected, with a mortality in the 7 benign cases of 28.6 per cent., and in the 28 malignant cases of 75 per cent.

From 1886 to 1890, 114 cases were collected, of which the mortality in the 14 benign cases was 35.7 per cent., and in the 95 malignant cases 48.4 per cent.

From 1891 to 1896, 401 cases were collected, of which the mortality in the 146 benign cases was 10.9 per cent., and in the 254 malignant cases 36.6 per cent.

Or, putting it differently for operative methods:

Wölfler's operation, 1881–96, 231 cases, of which the mortality in 26 benign cases was 19.2 per cent., and in 173 malignant cases 42 per cent.

v. Hacker, 1881–96, 152 cases, of which the mortality in 26 benign cases was 26.9 per cent., and in 115 malign cases 38.3 per cent.

If, however, individual experience is sought for as a guide or rather as an incentive, one may turn to Mikulicz's cases, 74 in number. Of these, 61 operations were for malignant growths, with 21 deaths, or 34.4 per cent. mortality; and 13 benign cases, with 3 deaths, or 23 per cent. mortality. Or Doyen's 40 benign cases may be looked at, with 8 deaths, or 20 per cent. mortality; and 8 malignant cases, with 3 deaths, or 37.5 per cent. mortality. These, with the miscellaneous collection above, give a summary like this: in malignant cases the mortality ranges, according to expertness mainly, from 34 to 37 per cent., and in the benign forms of gastric disease the mortality ranges between 10 and 20 per cent. But even better than this can be anticipated in the benign affections, for Carle and Doyen, who employ this operation, as before stated, in gastric lesions due to hyperacidity, etc., as well as in the conditions usually demanding it, have shown that in such cases the death rate is startlingly diminished—Doyen, the advocate of the complicated anterior operation, having had 18 gastrostomies for such troubles, without a single death; and Carle, employing a Murphy button with a posterior opening, having published 23 similar operations, with an equally brilliant result.

Without pursuing this interesting and by no means exhausted subject further, the following conclusions may, I think, be stated as being correct:

1. That gastro-enterostomy, as usually performed, is yet an unsatisfactory operation.

2. That its principal relievable danger is from bile or stomach retention due to operative defects either primary or secondary, *e.g.*, spurs, kinks, twisted or distorted openings, and possibly stomach atony.

3. That a posterior stomach opening favors gravity action by the evacuation of the organ particularly if it is atonied and diminishes the risk of pressure or of pulling on the attached intestine.

4. That the operation is best conducted by means of a Murphy button.

5. That a gastro-enterostomy associated with an entero-anastomosis in the afferent and efferent portions of the jejunum probably gives the best assurance against obstruction. Experience in this method, while so far gratifying, should, however, be enlarged to ascertain if the increased risk of the additional button overtops the danger of the bile and pancreatic obstruction.

SOME SUGGESTIONS FOR THE ORGANIZATION AND INTERIOR ECONOMY OF A STATE MEDICAL-MILITARY SUBDEPOT IN WAR TIME.[1]

By JOHN VAN RENSSELAER HOFF,
MAJOR, SURGEON, UNITED STATES ARMY.

"History is philosophy teaching by example." We have but to review it, and then glance about us at the current happenings, to be convinced that in spite of our boasted civilization man is instinctively a fighting animal, and war is always a probability.

While civilization has not eradicated and never will eradicate this instinct, it has so advanced our knowledge of things that war is no longer a mere question of the man—though this is the largest factor—but of the material, of the organization, indeed, of the numberless *inanimata* which make a part of the art of war.

These are not the creation of a moment, but follow careful preparation and accumulation, the results of experience, study, and opportunity.

We of the sanitary department have no small share in this work; indeed, it is an ever-increasing share—for civilization, while unable to subdue the fighting instinct, demands that the fallen shall be more and more carefully conserved; therefore it is important that our preparations *ab initio* be duly weighed and our plans determined upon before the event of hostilities.

In this connection we may well consider what will fall to the military authorities of the States, and our historical examples will be drawn from the war of secession.

During the years 1861–65 the total strength of the armies of the United States was 2,143,855,[2] recruited by the States as follows, viz.:

Maine	49,035	Michigan	76,218
New Hampshire	29,150	Wisconsin	73,865
Vermont	26,355	New Mexico	4,432
Massachusetts	98,803	Missouri	78,035
Rhode Island	13,688	Kansas	16,624
Connecticut	45,181	Nebraska	2,175
New York	334,784	Iowa	68,118
New Jersey	44,398	Minnesota	18,554
Pennsylvania	214,427	California	15,725
Delaware	7,888	Oregon	1,773
Maryland	24,954	District of Columbia	6,546
West Virginia	27,518	Colorado	3,697
Ohio	225,669	Nevada	1,080
Kentucky	43,550	Dakota	206
Indiana	150,177	Washington	964
Illinois	210,043	Tennessee[3]	20,394

Of this number at least six per cent.[4] was engaged in the sanitary work of the armies.

In other words, 128,631 medical and other officers and enlisted soldiers were on duty in the medical department between the fighting-line and the hospitals at the base of operations. This number is exclusive of the *personnel* of the various military general hospitals scattered throughout the country far away from the theatre of operations, and differing very little from general hospitals in civil life. These hospitals contained, in 1864, 318,000 beds, and their *personnel* numbered 31,860 officers and men.

For the purposes of this paper we have to consider only so much of the sanitary *personnel* as may be called "military," viz.: that part which is in immediate contact with the combatant forces in actual service—the part which, during the war of 1861–65, was mostly detailed from the combatant ranks in numbers which will never be known, and which probably represented a considerable portion of the forty per cent. difference between the paper and fighting strengths of our armies.

In any future war we may have, it is hardly to be presumed or desired that the requirements in men of the medical department will be met by depleting the fighting-line; so it is reasonable to assume that this department will be called upon to recruit and train its own *personnel*, and this of course will be done in large measure through the medical departments of the respective States.

If this is to be the case, and if the requirements of our last war be an index of future wars as to the number of sanitary recruits to be organized and instructed, it goes without saying that there must be some place where such preliminary organization can be made and such instruction given. This place may be called the State medical-military subdepot.

To meet the requirements of active service, each State will necessarily have a place of arms where recruits can be rendezvoused, outfitted, and drilled; where the required material can be gotten together; where companies and regiments can be organized; and where, finally, the State recruit, after being duly "mustered in," will become a soldier of the United States.

It need hardly be said that this place of arms should be located conveniently near the State's centre of population, and that it should be sufficiently extensive, both in area and plant, to meet all of the very important physical requirements of such a place under such conditions.

Cogent arguments might be advanced in support of the proposition that such an establishment should even now be in the possession of every State, instead of the comparatively few which thus far have been able to appreciate its advantages. Nor would it be useless to-day, when as yet war is only in the air, or even in times of profoundest peace, for it would serve admirably for the location of the annual camps of instruction now so generally established among our State troops.

This place of arms would in war time become the State general recruiting-depot, with a thorough military organization, and it is here the medical subdepot should be established. The organization of the general recruiting-depot cuts no figure in this paper, except so far as it touches the organization of the medical subdepot, which latter should be as nearly as possible independent. The subdepot should have a distinct and separate organization, the *personnel* of which, of course, would be under the orders of the depot commander (probably a general officer), though for administrative purposes only. The interior economy of the subdepot, the instruction of the men—in fact, everything pertaining to the sole object of the organization, the making of the sanitary soldier, should be in the hands of the subdepot commander—a medical officer—under the direction of the surgeon-general of the State.

Since we so emphatically claim the direction of the medical subdepot, we are under obligations to suggest some practicable plan for its organization and some scheme for its management. A very general consideration of these points is the *raison d'être* of this paper.

As the medical department must of necessity provide for the care of the actual sick—an ever-present entity—of the entire command, the first thought must be given to them, and temporary hospital accommodations supplied at the earliest practicable moment for at least two per cent. of the probable garrison. This so-called field hospital, of canvas, should be followed as soon as possible by a more permanent structure. *Pari passu* with the permanent hospital, there will be erected quarters for officers, barracks for men, storehouses, stables, bakery, mess hall, etc.—the various buildings pertaining to any community, be it civil or military.

[1] To be presented at the next meeting of the Association of Military Surgeons, United States.

[2] Fox says that reduced to a basis of a three-year term the total strength of our army was 2,327,917.

[3] Small numbers from other States make up the total.

[4] See articles on sanitary organization by the writer, published in the various proceedings of the Association of Military Surgeons, United States.

Happy the State which, even though it has not these buildings, has officers so far-seeing that plans and specifications for them have already been prepared and filed away for instant use when the emergency arises which requires it. If all these matters have been fully anticipated and prearranged so far as possible, it is not to be doubted that the necessary plant could be established on a comfortable working-basis in thirty days. In the mean time the permanent *personnel* could be assembled under canvas.

The work of the medical subdepot for which this more or less permanent *personnel* must be provided is to be considered under two heads, viz.: 1. The care of the sick of the garrison. 2. The instruction of recruits for the hospital corps.

The duties will necessarily be both administrative and executive. A word as to the meaning of these terms. In military parlance, administration means the direction or management of a body of troops. The administration formulates the regulations and orders to govern the command, which the troops execute.

The administration of the subdepot will require, beside the commanding medical officer, several other officers, non-commissioned officers, and private soldiers of the hospital corps, all of whom will be essential to its successful working.

The hospital department capable of permanently housing two hundred patients, with canvas for an additional two hundred, will require a numerous *personnel* hereafter to be considered.

The department of instruction will require approximately one officer to every fifteen men and one non-commissioned officer to every five men.

The details of the foregoing outline of our proposed subdepot may best be illustrated by assuming conditions quite likely to occur in any future war.

The latest available authority gives the population of the State of New York as 7,152,834, of which number one million men, more or less, may be assumed to be of the fighting-age (eighteen to forty-five).

During the war of 1861–65 this State furnished fifty-eight per cent. of its fighting population, and undoubtedly would do quite as well in any future war of equal magnitude. But to remain well within the bounds of probability, we will assume that New York's contribution to the next war will be 500,000 soldiers. We have already seen[2] that of this number six per cent., 30,000 men, will be required by the medical department. Should the war continue three years, we may safely estimate that the proposed medical subdepot of that State will have a probable average monthly strength of about one thousand men, exclusive of the sick of the station. Upon this estimate the organization of the medical subdivisions would, *mutatis mutandum*, closely approximate those of a regiment of the line.

War having been declared and requisition made upon the authorities of New York for that State's proportion of the number of soldiers deemed necessary by the President of the United States, among a thousand and one other orders, presumably even to-day carefully prearranged, one issues from State headquarters directing Colonel ——, assistant surgeon-general, New York, to proceed without delay to the general recruiting-depot, and there establish the medical subdepot. The objects of this special establishment are, as heretofore stated and as doubtless he will have been informed, the care of the actual sick of the entire depot and the preliminary organization and training of the sanitary *personnel* of the State's recruits.

Colonel ——'s special instructions, which doubtless he has received from the surgeon-general of his State, inform him that he is expected to select his own subdepot staff from among the officers ordered for duty there, to organize a station hospital, and the necessary number of companies of instruction. If the State has anticipated the moment of necessity therefor and established an adequate plant, or even if it has a detailed paper organization for the proposed subdepot, the responsible officer on the ground will be saved endless trouble. If, however, nothing has been done, he will of necessity have to start *ab initio*.

It is quite apparent that the first step out of chaos a commander can make is in the organization of his staff and the distribution of its duties, thereby leaving him free from the numberless details which would divert his attention from more important matters. Hence Colonel ——'s first duty will be to organize and locate the administration.

It may be assumed that the State military authorities will have so far anticipated the personal requirements of the proposed organization as to have directed the following, or as many of them as practicable, to report at the earliest moment, viz.:

Administration—1 lieutenant-colonel, medical department, executive officer; 1 captain, medical department, adjutant and medical supply officer; 1 captain, quartermaster's department, quartermaster, subsistence, and ordnance officer; 8 non-commissioned officers (3 hospital stewards, 3 acting hospital stewards, 1 quartermaster's sergeant, 1 commissary sergeant); and the necessary number of private soldiers as clerks, artificers, orderlies, drivers, conservancy, cooks, bakers, waiters, etc., probably about fifty—to be determined as the organization develops.

Upon their arrival at the station the officers are at once assigned to the indicated duty, and as many non-commissioned officers and men as deemed necessary are detailed to the respective departments.

In the mean time, the State authorities having determined the probable average strength of the garrison and notified the medical authorities, the first consideration of this department *in loco* is to provide hospital accommodation for the estimated sick of the command, which, as we know, will certainly not be less than two per cent. of its total strength.

Assuming that the average garrison will be ten thousand, the medical officer commanding the subdepot directs his quartermaster to require at once for tentage and other quartermaster's supplies to accommodate two hundred patients, say: hospital tents, complete, 54; wall tents, complete, 9; common tents, complete, 20; together with the necessary cooking and heating material, fuel, lighting, forage, horses, harness, ambulance and other wagon, clothing, equipage—in fact, everything except medical supplies, ordnance, and subsistence. Each tent should be floored with tongued and grooved flooring, and properly heated and lighted.

No department is more important than the quartermaster's; it is the *omnium gatherum*, from which one seeks everything that cannot be obtained from the very special supplies furnished by the other departments.

At the same time the officer in charge of medical supplies is directed to require for furniture, bedding, and other interior fittings; for medicines, dressings, surgical instruments and appliances, special-diet stores, etc.

The commissary officer arranges for the subsistence of the soldiers actually on the ground, and makes all preparations to meet the ever-increasing demands upon his department, which least of all can be ignored.

With the temporary station hospital thus prepared,

[1] On July 8, 1894, the plans and location of the great Japanese base hospital at Hiroshima were approved; on the 30th of that month the hospital, consisting of ninety-six separate buildings, capable of accommodating 2,555 patients, was completed.

[2] "Outline of a Scheme of Military Sanitary Organizations," Proceedings of the Association of Military Surgeons, United States, 1897.

the subdepot will be in admirable position to meet the requirements of the sick of the station, so soon as the *personnel* of the hospital can be assembled, viz.:

Nine medical officers (1 major-surgeon commanding, 2 major-surgeons, 3 captain assistant surgeons, 3 lieutenant assistant surgeons); 64 non-commissioned officers, men, H.C. (2 hospital stewards, 5 acting hospital stewards, 35 nurses, 4 cooks, 9 attendants, 9 medical officers' orderlies).

Pari passu with the temporary arrangements above outlined, plans and estimates will be prepared and contracts let for the construction of a more or less permanent hospital building of two hundred beds' capacity. This with the temporary canvas hospital in reserve will meet all demands that the sick of the station are likely to make upon it.

The probable needs of the sick having been fully anticipated and so far as possible provided for, attention may now be turned to the other important feature of the subdepot—the department of instruction.

We have heretofore seen that, in addition to the sick of the entire general recruiting-depot, the medical subdepot would have an average strength of about one thousand officers and men of the sanitary corps, the object of their assembly being their organization into and training for the various sanitary units required by an active army.

These units are: 1st, the station hospital; 2d, the ambulance companies of the hospital corps; 3d, the field hospitals.

Assuming that any man well trained in the work of the above organizations will be able to do his part in the regimental detachments or in the base or other military hospitals, such will need no further representation at the training-school.

The *personnel* of the administration and the station hospital having been assigned, there are left of the estimated strength of the subdepot about nine hundred officers and men to be organized into ambulance companies and field hospital detachments.

We have heretofore shown[1] that each ambulance company requires eighty-eight officers and men, and each field hospital sixty, including in both cases the transport *personnel*. Based upon this there could be organized six ambulance companies and six field hospitals.

These organizations must, of course, be properly quartered. Tents will meet the early requirements very well, but would prove expensive for prolonged use. In addition to those for the station hospital, more or less permanent structures must be provided, as follows:

One administration building, containing offices for the commanding officer and staff; 1 storehouse for medical, quartermaster's, ordnance, and subsistence supplies; 1 stable and wagon shed; 6 barracks for ambulance companies; 6 barracks for field hospital detachments; 1 mess hall, kitchen, and bakery; 1 soldiers' exchange building; 1 building for officers' quarters.

It will be observed that no provision is made for separate quarters for individual officers, nor is it believed that under the conditions such will be necessary.

Having so far as possible provided for the material wants of our proposed corps, let us now briefly consider what means shall be adopted to lay broad the foundation of discipline, training, and instruction which is to convert the crude recruit into the finished sanitary soldier. Much depends upon a proper beginning. If officers and men can be given a comprehensive idea of what they are expected to do, even though ignorant of the nice details, they will be by so much more efficient; add to this practice tinctured by zeal, and perfection will ultimately be attained.

Any one who reads even only what is here written must be convinced that there is something more to be done by the civil practitioner of to-day, who to-morrow may follow the drum, than pack his valise and join the procession. His knowledge as a physician is, of course, a *sine qua non*: but not so very far behind this is that knowledge which will enable him to supplement his own hands by those of others, and thus and thus only will he be able properly to care for the numberless sufferers thrust upon him within a day or even an hour. Nor is this all, for the conditions under which these sufferers must be treated are so different from those which obtain in civil life that his practice must be modified accordingly.

Revenons à nos moutons. Besides the general administration necessary to an aggregation of military units, each unit has within itself an administration which regulates the interior relations of its individual members. In a company this administration is represented by the officers and non-commissioned officers. The immediate commander of a unit is held responsible for the efficiency of his command, and to promote this efficiency he is given a certain number of assistants, who in military parlance are known as officers—commissioned and non-commissioned—whose duties within certain limitations he prescribes. Wagner says: "The most efficient armies are those in which the captains are given the greatest latitude in the methods of instructing and providing for their companies, and held to the most rigid accountability for their good condition and military efficiency."

Our proposed sanitary units must be organized on military models as above outlined, and the commanders thereof must be held to the same accountability. Unfortunately we have as yet no sanitary model and no standard other than that of the line.

Since such is the condition of affairs, how would a medical officer proceed who had received orders to organize and command an ambulance company? A military body is to be hewn out of some eighty or more intelligent citizens, most of whom will have no knowledge of what is expected of them. His first step would be to make his *cadre* or framework. Doubtless two or three physicians who had been appointed officers, and who will make up in zeal what they lack in knowledge of the work in hand, have already reported to the company commander: these, with the senior non-commissioned officer—whom the commander selects from among the men and who is practically the company adjutant—form the foundation of the frame, the superstructure of which is the remaining non-commissioned officers. Considering the work and equipment of this company, there is room in it for a non-medical officer—who might be called the quartermaster—who would rank as a first lieutenant and have charge of the property and transportation.

The frame having been completed, no matter how temporarily, the details are to be fitted therein. The company should be divided into two platoons, each under a medical officer, and a transport detachment, the latter to consist of 3 non-commissioned officers, 2 artificers (1 blacksmith, 1 saddler), 1 bugler, and 17 privates (14 drivers, 1 cook, 2 supernumeraries), under command of the quartermaster.

It may be that the details will not at first fit the frame with accuracy, but they will do so at least ap-

[1] The *personnel* should be distributed as follows: For each ambulance company, 3 medical officers (1 major surgeon commanding, 1 captain assistant surgeon, 1 first lieutenant assistant surgeon); 1 quartermaster (first lieutenant); 16 non-commissioned officers, 2 buglers, 2 artificers, and 64 privates, H.C. For each field hospital, 3 medical officers (1 major sugeon commanding, 1 captain assistant surgeon, 1 first lieutenant assistant surgeon); 8 non commissioned officers, 1 artificer, and 42 privates, H.C. See Proceedings of the Association of Military Surgeons, U. S., 1897, p. 437 *et seq.*

proximately, and in due time, with judicious trimming, perfectly.

As new men join the company, they can at once be assigned to one or another of the subdivisions and fall into their proper places.

The field hospital detachments will, *mutatis mutandum*, be arranged on the same lines—the sixty or more individuals constituting such being so subdivided as best to accomplish their work. The transport detachment with this organization will consist of 4 non-commissioned officers, 1 artificer (blacksmith), 12 privates (10 drivers, 2 supernumeraries).

Thus far we have provided a place of rendezvous and a habitation. We have anticipated the material requirements of the men of the proposed sanitary corps as to food, clothing, and equipment, and we have assigned them to organizations. It now remains for us to consider the best method of discipline, training, and instruction we can adopt to fit them for their work.

It may be safely assumed that, for the most part, the recruits assigned to the hospital corps will have had some training in civil life as druggists, clerks, nurses, mechanics, hostlers, cooks, etc., which would cause their selection for this special corps and more or less prepare them for its peculiar duties. This, added to the fact that "with intelligent and zealous volunteers discipline becomes mainly a matter of instruction and guidance," will make a well-considered scheme of training comparatively easy of execution.

In the beginning of hostilities it is not probable that any State will be able to hold its men for more than one month's training, when it will be called upon to send complete organizations into the field. Later, when a sufficient number of sanitary units have been supplied, it will only be necessary to keep up their strength, and the units of instruction will become more or less permanent, the officers and men attached being detached when required.

The training of the sanitary soldier must be military as well as technical, for it goes without saying that he must be a soldier, thoroughly disciplined and especially loyal to his duty. His work is most frequently done upon his own responsibility and away from the watchful eyes of his superiors; moreover, it is often done under circumstances of extreme danger, without the support of "touch of elbow" and the comforting thought which the fighting soldier has that, come what may, he can "give as good as he gets."

Any one who thinks that a man without a gun cannot be a soldier, even though he does and dares all that any man can, is hardly in accord with the public sentiment which responded so warmly to the story of Piper Findlater at the charge on Dargai Ridge.

True discipline being the object sought, certainly no method of its attainment can be equal to the military method, since this is the concrete result of experience in discipline from the earliest times even until to-day. Therefore, our recruit must be trained as is any other; he should be carefully "set up" and thoroughly drilled in the school of the soldier and the company, so that he will understand and be able accurately to execute all the movements therein described. He should be taught the manual of arms and the use of the rifle, "for, though he will ordinarily neither carry nor use firearms, it is held that no man can be a soldier who is unfamiliar with them;" moreover, it is universally recognized that nothing so quickly teaches unquestioning and ready obedience to orders as frequent exercise in the manual of arms. There is something seriously suggestive about a rifle that does not attach to apparatus for light gymnastics.

Another exceedingly important part of the military training is to teach the recruit how to care for himself under the peculiar and varying conditions of his new life. This comes to him through the company housekeeping, for in the field each organization takes care of itself, cooks its own food, makes its own beds, does its own policing (cleaning up); in fact, a military company may be considered as a family, the head of which is the commander, who is the director, instructor, provider, and dispenser. The commander should regard his men as does a father his children; and they in turn should render him the respect and implicit obedience due from a son to his father.

Certain modifications of the company housekeeping while it is at the subdepot would probably be found desirable; there a general mess for the entire command (except the hospital) would be more convenient. This mess should be so conducted as to serve as a school of cookery, in which the largest possible number of non-commissioned officers and men of each organization should be given an opportunity to gain a practical knowledge of the management and cooking of the ration.

The technical training of the sanitary soldier will be imparted through lectures, recitations, demonstrations, and practical work. He must be thoroughly taught first aid and nursing, which include a sufficient knowledge of simple anatomy, physiology, pharmacy, diet cooking, bandaging, etc.; he must know the appliances of the medical department, particularly those pertaining to the field. His instruction in field work becomes of the utmost importance, since his duties will be performed under active service conditions. Pitching and striking tents, loading and unloading wagons, the particular work of the various sanitary units, the care and driving of animals, etc. Bearer drill, the purpose of which is to teach the best method of transporting the ill and injured, is a very important part of this training.

Of course, all this can only be outlined here, but certainly enough has been written to show that the men we must have are no more or less born than any other soldiers; they must be made, and can be made only by the most careful selection and training.

If only for purposes of instruction, it would be desirable that the equipment for at least one ambulance company and one field hospital, complete in the minutest detail, be supplied the subdepot, so that all could learn the material and its uses.

The routine of a day's work would be somewhat as follows: 5 A.M., reveille; 5:15 to 5:30, "setting-up" exercises; 5:30 to 6, breakfast; 6 to 7, fatigue; 7 to 8, study hour; 8 to 9 infantry drill; 9 to 10, recitation in nursing; 10 to 11, study hour; 11 to 12 M., recitation in first aid; 12 M. to 1 P.M., dinner; 1 to 2:30, bearer drill, litter, ambulance, travois, etc., as soon as possible combined with first aid; 3 to 4, formation of ambulance and dressing stations, alternating with the pitching of the field hospital; 4 to 4:30, practical bandaging and splinting; 5 to 5:30, supper.

As soon as the men become sufficiently informed, a certain number of them would be detailed each day in the station hospital for practical instruction with the actual sick, and in the interior economy of military hospitals. Certain others would be detailed in the mess hall and kitchen, and yet others in the other departments of the subdepot, until a fairly comprehensive knowledge of the required work would be gained. With such preliminary training, the sanitary recruit would join his permanent command with an intelligent appreciation of what would be required of him—certainly an immense advantage to him and to the service he will form part of.

The chief object of the foregoing remarks is not to offer the best plan for organizing a State medical subdepot, but rather to call attention to the fact that some such organization will be necessary.

Our country cannot again afford the time, the blood,

and the treasure spent during the first two years of our last war to learn how to care for the wounded of the next; neither can we begin where that war left our sanitary organization, admirable as it then seemed. A generation has passed since then, and military sanitation has no more "marked time" than have other arts. The ambulance corps of that day, taken from the fighting effective; hospital attendants detailed from the line regiments as the situation demanded, or improvised from convalescents—excellent as was that improvisation, by comparison it was but a step in the evolution of a sanitary corps, and will no more be permitted in our next war than will the surgical procedure used in the last. Our sanitary corps must be distinct and separate from all other branches of the service; its organization and training must begin with the State medical departments, and its recruitment must be continued by them. Ambulance company No. 50, New York, will be just as distinctive in that State as the fiftieth regiment of volunteers, New York; and field hospital No. 35, New York, as light battery B, New York artillery.

By some such organization, and only such, can our sanitary corps reach the highest efficiency.

Vancouver Barracks, Washington,
March 17, 1898.

REMARKS ON RHUS TOXICODENDRON.

By LOUIS F. FRANK, M.D.,
MILWAUKEE, WIS.

About two months ago my attention was drawn to an article written by Mr. Bernhard Ziehn, the well-known musician of Chicago, likewise an authority on botany, in which the earnest consideration of the city authorities was called to the fact of the existence and flourishing of the Rhus toxicodendron in the various parks of Chicago, advocating radical measures against the alarming condition.

In Lincoln Park, in the neighborhood of populated streets, Mr. Ziehn localized seven wild ivy plants, one of them with at least twenty roots encircling an oak tree, thirty feet in height, sending its shoots to the very top of the tree. In Washington Park, near its northern entrance, he found a tree, twelve feet in height, loaded with the poisonous fruit, and a shrub with a trunk the size of an arm. A similar condition of affairs was discovered in the Jefferson, Union, Garfield, and Douglass parks of Chicago, and in all places north of Chicago toward Evanston. The agricultural department at Washington, learning of the efforts of Mr. Ziehn, requested him to continue the same and keep it informed as to the progress made. Moreover, as Mr. Ziehn during a visit to Milwaukee discovered the plant in "The Ravine" and other places in Lake Park, he asked my co-operation in the matter, which I, convinced of the importance of the subject, decided to bring before the profession. Not a year has passed but I have been called upon to treat a number of cases of dermatitis caused by one or other variety of the Rhus species, and no doubt it has been not an unfrequent occurrence in the experience of the general practitioner.

Dr. White, of Boston, in a review of three hundred and sixty cases of dermatitis treated in his clinic during the past two years, has found thirty, or nearly ten per cent. of them, to have been caused by the so-called wild ivy.

It is well known that the vegetable kingdom furnishes many substances which, when in contact with the skin, occasion irritation and more or less severe inflammation. According to the virulence or concentration of the poison and the susceptibility of the skin, the lesion will be erythematous, vesicular, pustular, or bullous in character. Among these plants may be mentioned nettle, mezereon, arnica, common parsnip, witch-hazel, hop, hornbeam, and, above all, the species Rhus toxicodendron and Rhus venenata, a genus of the common sumach. The former, Rhus toxicodendron, by earlier botanists and more properly called Rhus radicans (Fig. 1), is a vine of very common oc-

Fig. 1.—Poison Ivy (Rhus radicans).

currence, running over stone fences and along the borders of woods, in ravines or climbing on to trees to a considerable height and attaching itself to these surfaces by lateral rootlets. It is popularly known as poison ivy, poison vine, poison oak, mercury, and is found abundantly throughout the United States east of the Great Plains, and in the arid regions of the West, with the exception of California. It is generally a

Fig. 2.—Poison Sumac (Rhus vernix).

climbing vine, but if no support is at hand it either trails along the ground or sends up short vertical shoots. With the exception of one near Western relative, which is almost as poisonous, there are no other plants which resemble it closely, excepting the non-

poisonous box-elder, and this only in its seedling stage. The Virginia creeper, also non-poisonous, is sometimes mistaken for the poison ivy, but is easily distinguished by its having five instead of three leaflets.

The second variety, Rhus vernix, or poison sumach (Fig. 2), also commonly known as poison dogwood, poison ash, and poison elder, is found growing in swamps from Florida to Canada and westward to the Mississippi Valley. It is a shrub or small tree, six to eighteen feet in height, with long pinnate leaves, having from seven to thirteen smoothly polished leaflets.

The third variety, of near resemblance to the first-named Rhus radicans, is known as Rhus diversiloba, or poison oak (Fig. 3), and is found only throughout

Fig. 3.—Poison Oak (Rhus diversiloba).

the Pacific coast from Lower California to Canada and northward. The leaves differ in size as well as in shape from those of the poison ivy.

The first and second varieties, therefore, Rhus radicans or toxicodendron and Rhus vernix, are of special interest to us, as the same are indigenous to Wisconsin.

It has generally been accepted up to to-day that the poisonous irritant in the various species of the Rhus family was due to an active principle, consisting in a volatile acid, called toxicodendric acid. This was found in 1865 by John M. Maisch, of Philadelphia, and is to-day regarded in the United States Dispensatory as the active principle of Rhus. During the last three years, however, Dr. Franz Pfaff, of the pharmacological laboratory of the Harvard Medical School, has made a series of very interesting analyses and experiments, which not only criticise the imperfect manner and non-scientific results of Maisch's investigations, but also seem to prove that the principle is not a volatile acid, as thus far recognized, but consists of an oil, for which Pfaff proposes the name toxicodendrol. This poisonous oil has been found in all parts of the plant—in the stems, branches, roots, leaves, and fruit—its amount, however, varying, the fruits containing 3.6 per cent., the leaves 3.3 per cent., and the stems and branches only 1.6 per cent. The oil is easily soluble in alcohol, ether, benzol, chloroform, etc., but is insoluble in water. The effect of the isolated oil upon the human skin is described in the second number, 1897, of the *Journal of Experimental Medicine*, the experiments producing a clear, clinical picture of a dermatitis venenata.

I communicated with Dr. Pfaff, and he kindly forwarded to me a specimen of the toxicodendrol in its crude state, which was extracted from a fresh lot of Rhus venenata and had not yet been tested. He informs me that the pure oil is of a pale yellow color, exceedingly poisonous—to such an extent that the smallest quantity of the oil, unable to be detected by the unaided eye, would cause all the characteristic lesions of wild-ivy poisoning. It seems to me that the specimen sent to me is incapable of producing a dermatitis, as I have applied it thoroughly on my arm on two different occasions, likewise on the forearm of my druggist, without inflammatory result. Possibly neither of us is susceptible to the poison, and further experiments are necessary to prove its efficiency. However, the free purified toxicodendrol has in Dr. Pfaff's hands never failed to produce an irritant action.

The active principle, according to Dr. Pfaff, being a non-volatile substance, the question arises as to the commonly accepted idea that poisoning may occur without actual contact with the poisonous plants. Pfaff disputes this view, believing that actual contact with the poisonous oil is essential to produce the skin lesions, rendered extremely easy by the great activity of the poison and the latent period of development. None of the hundreds of persons that passed through his laboratory during the time that these plants were handled were poisoned unless they came into actual contact with the plant or the free oil. Nevertheless, the popular opinion prevails that the actual touching of the plant is not necessary to produce the eruptions; that the emanations at night time are particularly dangerous; and it has been maintained that persons may be poisoned by the exhalations into the room while the wood is burning in the fire.

I have read of several reports of cases in which the poisoning was produced by a peculiar Japanese lacquer, made from the Rhus vernicifera, not only in those actually engaged in lacquer work, but in those who live or sleep in rooms in which fresh-lacquered goods are drying. Especially children, after a night's rest in a room in which a newly purchased chest of drawers has been placed, exhibit symptoms of poisoning the next morning.

The question is still an open one, and scientific experiments must be resorted to in order to decide it satisfactorily. Personally, I am inclined to believe that a great many of the above-cited cases are of the "hearsay" order and cannot be accepted as undoubted evidence. The poison of Rhus toxicodendron may be communicated by direct contact with parts of the plant, or indirectly from one person affected to the other. The former method includes the great majority of all cases. The following two cases may illustrate the manner in which one person may communicate the poison to another.

The first is described in an article written by Dr. White,[1] reporting a fatal result in consequence of the poison. "A servant boy, being insusceptible to ivy poisoning, had been employed in pulling up all the vines of that plant found growing in the grounds about the house. When his task was finished, he was made to wash his hands thoroughly with hot water and soap and afterward with vinegar. In the afternoon he was allowed to take the six-year-old child of the family to a pond for a bath. Having stripped the child, he immersed him, holding him with his hands under the armpits, and afterward rubbed his back with his open palm. After three days deep ulcers formed under the armpits and every part touched by the hands showed the characteristic marks of wild-ivy poisoning."

Another case, reported by Dr. Cantrell,[2] shows how the poison was conveyed to the umbilical region of a

[1] New York Medical Journal, 1873.
[2] Medical News, 1891.

female patient of the Philadelphia Hospital, a vesicular and bullous eruption having a radius of five inches, œedmatous and covered with a yellowish-brown discharge, appearing three days after confinement. Upon inquiry it was learned that on the day of birth the attending nurse, taking a stroll through an adjacent cemetery, had gathered some leaves, bringing a number back with her. The ivy poison was in all probability conveyed to the patient during the time of dressing, although the hands of the nurse had been previously washed several times with soap and water. Her hands, at that time showing no signs of infection, became affected two days later, at about the same time the eruption appeared on the abdomen of the patient.

A third case is mentoned by Dr. Busey,[1] in which a family, consisting of both parents and an infant, was affected at the same time, the mother having a severe attack quite general over the whole body, the husband a similar eruption on both hands, and the infant a slight one about the mouth and chin. A week previous to the appearance of the eruption, the husband and wife had passed an afternoon at a picnic and he had fastened his horse to a bush covered with a vine, the character of which he had not observed. The wife did not approach the plant and the child had been left at home.

Dr. J. B. Walker[2] reports the fourth case I have found in the literature of poisoning by indirect contact. "A lady spent the night with her sister, whose husband was obliged to be absent on business. The husband had been poisoned about the head and neck with ivy, a few days before leaving home. The pillow case on which he slept was not changed, and his sister-in-law, using it, became poisoned about the face and neck in consequence thereof."

The disease usually begins on the hands, the inner surfaces of the digits being first affected, whence it spreads on the dorsal and later on the palmar surfaces. From the hands it is usually communicated to the face and the genitalia, and may from there come in contact with the entire body. The eruption generally appears in an erythematous form, accompanied by vesicles, pustules, and even abscesses, and it is attended with more or less œdema, swelling, heat, and itching. The serous infiltration may be so great as to occasion great disfigurement, especially of the hands, arms, and genitalia. The vesicles are usually small and often develop into pustules, which may rupture, the discharge drying into yellowish crusts.

The remedies that have been recommended for the treatment of Rhus poisoning are almost as numerous as those for eczema. Among the domestic remedies vinegar and solutions of saleratus and carbonate of sodium are widely and highly esteemed. I noticed a glowing account of the efficiency and virtue of buttermilk and pounded crabs in Japan as a remedial agent. Among the medicinal remedies the following have been advocated: astringent lotion of acetate of lead, sulphate of zinc, alkaline solution of lime water, ammonia, and hyposulphite of sodium, decoctions of white and black oak bark, Virginia snake-root, chestnut leaves, solutions of the fluid extract of grindelia robusta, calomel (black wash) and sublimate, emulsion of bromine, dusting-powders, and an array of ointments.

The use of dusting-powders, oxide of zinc, starch, magnesia, talcum, etc., I cannot recommend as practicable. Certainly they produce a rapid cessation of the serous discharge and a drying up of the same, but, mingled with the pathological and normal secretions of the skin, a layer of putrefying, decomposing crusts is formed, which tends to increase the inflammation. The same may be said of applications of ointment or plasters, as fats in the acute stages of a dermatitis are often not well borne: ointments of lead are especially bad, whereas Lassar's salicylic paste rarely is found to irritate the lesion. The treatment of any toxic dermatitis must be carried out on the same basis as that of eczema in its acute or subacute state, and the essential principle which ought to guide us in its successful treatment is antisepsis and asepsis. We know that a local infection has taken place: the poison has been absorbed by the skin, causing a pathological lesion, which is attended by inflammation and its sequelæ—exudations, crusts, and scales. These disease products are usually still more contaminated by external irritants, as salves, oils, and infected dressings. Plainly there seems but one thing to do: to follow out the principles of modern surgery, viz., to remove all products of infection and render the diseased part aseptic, and naturally the first indication is a cleansing bath with soap and water. And, strange as it may seem, what has been imperative in surgery has hitherto been but reluctantly followed in dermatology, the statement of Pindar, "Water is truly the best," being ignored. It is a popular notion, for instance, that infants affected with intertrigo and its sequelæ, dermatitis and eczema, must be prohibited from bathing, and strangely enough this view is shared and supported by many physicians. It is hard to believe that any one can sanction the presence of effete material consisting of the products of the perspiratory and sudoriparous glands, in the process of decomposition, to remain and act as inflammatory irritants. Basing on this simple and rational theoretical view, I have treated in the above manner all cases of dermatitis incited by external irritants, with far better success than by my former methods following the routine treatment. The bath is followed by applications of soothing antiseptic emulsions containing calamine, glycerin, and lime water, and so forth.

Having concluded the clinical aspect of the subject, it remains for me to speak of the importance of the prophylactic and legal measures to be taken in order to counteract and eradicate the harmful disease-producing plant. Although the name wild ivy is familiar to almost every one, the plant is so little recognized, as a rule, that contagion takes place when it might be easily avoided if the plant was better known. In this connection also I wish to mention the necessity of knowing and recognizing all poisonous plants indigenous to our soil, such as the datura stramonium, hyoscyamus, digitalis, lobelia, solanum nigrum, conium, aconite, hellebore, ricinus, clematis, colchicum, the buttercup, water hemlock, daffodil, narcissus, and varieties of fungi.

This important knowledge should be imparted in our schools, and I well remember seeing during my stay in Germany charts in the schoolroom, illustrating in color the various poisonous plants of that section of the country, in order to familiarize the children with their characteristic appearances. Furthermore, the teachers would accompany their classes into the woods and meadows, calling their attention to the species and properties of plants by intuitive instruction.

The number of deaths which occur every year from incautious eating of poisonous plants, as described in a report of the agricultural department, is very large. The victims are usually children, who pluck and eat all sorts of attractive-looking berries and other parts of plants. A special commission was appointed about three years ago by the bureau of agriculture to investigate poisonous plants and enlighten the public as to their danger.

According to a government report on health, 1884, a peculiar disease in children, characterized by extreme weakness, vomiting, fall in bodily temperature,

[1] American Journal of the Medical Sciences, vol. xvii.
[2] Medical News, 1891.

dry tongue, and constipation, is said to be prevalent in some Western States, which is supposed to be produced by cows affected with the "trembles" caused by feeding on wild ivy.

In my efforts of investigating this subject as to its legal aspect I was very kindly assisted by Dr. U. O. B. Wingate, secretary of the Wisconsin State board of health, and I take this occasion to thank him for the interest he has shown. There exists at present in this State a law amended at the last session of the legislature, known as chapter 82, 1897, pertaining to noxious weeds, not, however, naming the Rhus plant in particular. Dr. Wingate, in order to ascertain whether such law would include the plant in question, kindly furnished me with the opinion of the attorney-general as to the law on this point, viz.:

"Relative to the destruction of noxious weeds, it is my judgment that any person has the right to destroy the weeds designated as noxious, when found in public parks and other public places.

"The law provides that the persons in control of lands shall be given notice of the presence thereon of noxious weeds, and they must be destroyed within a certain specified time thereafter, or the persons so notified shall be subject to penalty.

"Notwithstanding this provision, it seems to me that the poisonous weeds which may be found and whose presence may be a menace to public health, as indicated by your letter, may be destroyed by any person, for the reason that they would be deemed by law to be public nuisances, and as such subject to immediate abatement by any person knowing their character. The reason for the destruction of these by persons having knowledge of their character is to prevent the destruction of vegetation which is not noxious in its character, and those who destroy noxious weeds must be careful and not injure surrounding vegetation, for by so doing they would render themselves liable.

"It certainly is within the province of a board of health forthwith to destroy, or order destroyed, such weeds as may be dangerous to the public health, and this right it has in its general right to take such measures and use such precautions as may be necessary to protect the health of the people."

The information above given makes any commentary unnecessary and clearly places all right of jurisdiction in the hands of the authorities on health. Active measures taken in this respect and a publication of such facts cannot fail to be of invaluable service to the many thousand persons who are brought into almost daily contact with the plants, and cannot be too highly recommended and demanded.

2300 Grand Avenue.

Longevity of Germs in Dust.—In a recent number of the *Annales de Micrographie*, Dr. Miguel gives the results of some interesting observations made by him in respect to the vitality of disease germs. In May, 1881, he took some earth from the Montsouris Park, at a depth of ten inches below the turf. This he dried for two days at a temperature of 30° C., and then he placed the dust in hermetically sealed tubes which he put aside in a dark corner of the laboratory. When taken, the soil contained an average of six and one-half million bacteria per gram. After desiccation the number had fallen to rather less than four million. Sixteen years later—that is to say, last year—he still found three and one-half million per gram, and he was enabled to isolate the specific microbe of tetanus. The inoculation of this soil in guinea-pigs determined death from tetanus after an incubation period of two days, showing the remarkable vitality of pathogenic microbes under favorable conditions.—*Medical Press.*

ON THE VALUE AND LIMITATIONS OF THE ELECTROLYTIC METHOD OF TREATMENT, WITH SPECIAL REFERENCE TO SUBCUTANEOUS NÆVI AND URETHRAL STRICTURE.

By A. D. ROCKWELL, M.D.,
NEW YORK.

The electrolytic method of treatment gave promise in its early surgical history of a rather brilliant career. It was claimed that many surgical diseases which the knife failed permanently to relieve would yield radically to this new and fascinating process. The pains of scirrhus cancer are sometimes greatly ameliorated by proper methods, and not infrequently absorptive processes are excited that result in an appreciable diminution in the size of tumors, both malignant and benign.

When electricity came into prominence twenty and more years ago, it is a matter of record that the writer experimented largely in the treatment of malignant growths of almost every description, and, while it was demonstrated that most gratifying alleviation of symptoms often followed, it was as clearly demonstrated that electrolysis was incapable of favorably influencing to any extent the prognosis of the graver forms of malignant growths. More recently it has been asserted that sudden voltaic alternatives, flashed with inconceivable rapidity through a cancerous growth, under a pressure as high as six hundred milliamperes, would extinguish the low vitality of the cancer cells. Repeated efforts have, however, failed to show that more has been accomplished by this method than by the older one.

But while the limitations of electrolysis are distinct and positive, it has yet a field of its own, which, by intelligent cultivation, yields results both valuable and unique. More specifically, the electrolytic treatment of uterine fibroids is generally followed by a certain amount of reduction. Unlike an external fibroid tumor, an internal tumor is treated, not because it is unsightly but because of its associated and sometimes distressing symptoms. The most electrolysis can do for fibroid growths is to reduce them somewhat in size, and there is therefore but little occasion for such interference when the growth is external.

A fibroid tumor of the uterus, however, even though it be small, often gives rise to a great variety of distressing and disturbing symptoms. It is quite remarkable how many of these symptoms—pain in micturition due to pressure, rectal difficulty also due to pressure, dysmenorrhœa, menorrhagia, and even impaired locomotion—disappear even after a very slight reduction. If, therefore, for any reason a radical operation is impracticable or is not permitted, we have in electrolysis a method of considerable value. Still the results are too often only palliative, and it is more than doubtful whether either electrolysis, or what is termed galvanochemical cauterization, ever entirely dissipates a uterine fibroid.

The one surgical condition, and perhaps the only one aside from certain facial blemishes, moles, superfluous hairs, etc., in which electrolytic treatment approaches the dignity of a specific, is the familiar nævus maternus—the erectile or vascular tumor of infancy. Reference is not here made to the superficial or cutaneous forms of nævi. These wine-mark stains, consisting of widespread dilatation of cutaneous vessels and attended by little swelling, have indeed been often treated by the electrolytic method, and in many cases with decided benefit. The measure of benefit is, however, varying, and, if the stain is large, is obtained only after long and tedious treatment, and with considerable resultant scar. The form of nævus to which allusion is here made is of

the subcutaneous variety, to which has been given the name of aneurism by anastomosis. These subcutaneous nævi, filled with blood and intensely hemorrhagic, are generally much dreaded in operative surgery, and are therefore often allowed to remain and develop, notwithstanding the fact that we have at our command a procedure comparatively simple and entirely bloodless, sure in its results, and leaving no disfiguring scar. The importance of this, when the patient is a girl and the site of the tumor the face, is apparent.

The writer has during the past twenty years treated quite a large number of these erectile tumors by the electrolytic method, and with almost uniformly satisfactory results.

The object is to induce firm coagulation, which, when left to nature, is gradually absorbed. A point of some interest relates to the time consumed in this absorptive process. As a rule, the tumor rapidly decreases in size during the first few weeks, but subsequently absorption takes place more slowly, and in some cases it is many months before the enlargement entirely disappears. In other cases the results are far more rapid. To illustrate this simple electrolytic method as well as the extreme rapidity with which in favorable instances the coagulated mass disappears, I offer the following recent case:

Case I.—Mary G——, aged eleven years, was brought to me by her parents, October 6, 1896. She had two bloody tumors, one located on the left cheek just above the angle of the lower jaw and the other on the upper lip. The one upon the jaw was quite large, measuring in diameter at its base some three centimetres and in depth about two centimetres. Speaking by comparison, its size was about that of an English walnut. The second tumor was much smaller, but involved the interior of the nostril as well as the external tissues. Both tumors were soft and readily compressible, and were unmistakably increasing in size. The patient having been anæsthetized, three platinum needles, insulated to within about one-third of an inch of their points and connected by means of a serres-fines conductor with the positive pole, were thrust at equidistances from each other into the body of the tumor.

The negative electrode, three inches in diameter, consisting of moist sculptor's clay, was applied to the upper part of the arm near the shoulder. The current was then gradually increased until the milliameter registered sixty. In a few moments the surface redness assumed a dull color, and as the blood coagulated the tumor hardened and increased slightly in size. At the end of ten minutes firm coagulation had taken place, and the needles were withdrawn without loss of blood. The same process was then applied to the other and smaller nævus, one needle only being introduced, and with a similar prompt and efficient result. No inflammation and no pain followed, and on January 2, 1897, less than three months after the operation, when the patient was seen for the last time, hardly a trace of either tumor remained. This seems a very simple and easy process, and so it is; but, like all operations that are simple and easy when one knows how, it demands a certain amount of knowledge, care, and judgment. Two principal causes of non-success consist in doing either too little or too much. If the current is of insufficient strength, or its action not sufficiently prolonged, complete coagulation fails to take place; the circulation may become reestablished and the work has to be done over again. The results of an overdose or a too prolonged action may be disagreeable in the extreme. Irritation and suppuration may occur, with possible degeneration into an ulcerative process, and while the ultimate result may be a cure an unsightly and unnecessary scar remains.

It should be distinctly understood that the operation ought not to be attempted on a child whose health and strength are for any reason very much impaired. My earliest experience in the treatment of this condition was among hospital and dispensary cases, and in two of these cases the operations, although conducted with great care, resulted in considerable ulceration, which gave not a little trouble and left behind considerable scars. In cases of impaired or perverted nutrition, improve the condition of the child by tonics, proper feeding, air, and exercise before resorting to electrolysis.

The differential chemic and cataphoric action of the anode and cathode has been so often pointed out and ought to be so thoroughly understood that it seems at first thought hardly necessary to reiterate. But he who does much in this line not infrequently encounters the evil results due to ignorance of polar action. A young lady came to me recently with her chin quite thickly dotted with minute dark blue spots, of which she did not know the meaning, only that they appeared after several electrolytic treatments for the removal of superfluous hairs. The operator had connected his needle with the positive pole in utter and unjustifiable ignorance that oxygen accumulated at this pole, and that the staining of the tissues was due to the oxidation of the steel, of which the needle was made. Again, while I have little confidence in the use of electricity for the cure of urethral stricture, yet so many are led to use it because of the enthusiastic reports as to its efficacy that a correct appreciation of the differential action of the poles is absolutely necessary in order that the patient may be preserved from harm, even if no good is accomplished. I am cognizant of several cases in which the positive pole has been used instead of the negative for urethral stricture, resulting in prolonged and painful irritation. The galvanic or direct current, as it is variously called, is a current of chemic action. At the positive pole or anode where it comes in contact with living tissue are deposited or evolved acids with oxygen and chlorine, while at the negative pole or cathode alkalies and hydrogen are set free. At the anode, therefore, are developed phenomena very different from those occurring at the cathode. At the former we get coagulation and a shrinking of tissue that continues for some time after the cessation of all electrolytic action, while at the latter there is a tendency to liquefaction and softening with acceleration of absorption. In both cataphoresis and interstitial electrolysis we necessarily develop the peculiar chemic and physical action of the anode, which in the one case simply causes medicated solutions to penetrate the skin so as to produce absorption and local anæsthesia, while in the other it first oxidizes the metal selected, whether zinc or copper, and then forces the resultant particles into the surrounding tissue.

In the treatment of most facial blemishes—moles, warts, hairs, etc.—the negative pole is alone admissible. In the treatment, however, of erectile tumors and in all hemorrhagic conditions the positive pole is to be used, because of its power to induce firm and complete coagulation.

If any one is credulous enough to believe that he can accomplish much by the electrolysis of urethral stricture, he must use the negative pole with a current strength not exceeding five or six milliamperes and a short *seance*, the shorter the better, so that no harm may come to the patient at his hands. Small cystic tumors have been successfully treated electrolytically through the caustic action of the negative pole upon the secreting membrane. It is probable, however, that the positive pole would prove equally efficacious, were the operation rendered harmless by the use of a non-oxidizable electrode.

Without in any way reflecting upon the honesty of those who believe that electricity when properly applied is equal to the cure of urethral stricture, I desire most emphatically to express a contrary opinion. I do not deny that benefit may sometimes follow such treatment, but it follows because of a gradual dilatation through the exercise of force, and sometimes I doubt not a spasmodic stricture has been mistaken for a cicatricial contraction. My disbelief in the curability of urethral stricture by electrolysis is based, first, upon the fact that it is irrational and contrary to such laws of electro-physics as are applicable in this condition; and, secondly, upon the results of a considerable personal experience. It would not, I admit, be so irrational were we able to concentrate upon the stricture itself without damage to the normal tissue a sufficiently strong current. This, however, we cannot do, and therefore three to five milliamperes, a strength of current which if used judiciously may do no harm, is now advised as the limit.

In reading the reports of the hundreds of cases of urethral stricture that just seem to melt away upon the application of three or four milliamperes of electricity, I am reminded of some of the extravagant reports in regard to the quick and complete disappearance of uterine fibroids under electrolytic action. Now, every one knows that a fibroid tumor situated on the outside of the body cannot be dissipated by electrolysis. It may decrease a little in size, and that is all; unless the treatment is so violent as to excite an active suppurative process, when the decrease is somewhat greater through an actual loss of substance. Why should an internal fibroid act so radically different under the treatment? As a matter of fact it usually does not, and the main reason why electrolysis is a method of some value in uterine fibroids, as before stated, is because of the great relief that often follows a very slight reduction in size. The tumor is still there, but the patient becomes symptomatically much improved. Similarly, a cicatricial contraction or a scar on the surface of the body is not influenced in an appreciable degree by any such insignificant current strength as three to five milliamperes, and so it is one of the mysteries why the definite chemic action of electrolysis should be so different when substantially the same condition is transferred to the dark and hidden recesses of the urethra.

Is a Violent Death Painful?—Severe injuries to the body are seldom very painful at first. The severity of the nervous shock seems to paralyze the nerve centre where consciousness of pain is situated, and in fatal cases there is often no sense of pain, even when death is delayed a day or two. In such cases it may be supposed that the shock not only paralyzes but even destroys the nerve centre. It may be compared to a lightning flash along the telegraph wires, which, although of the same nature as the electric telegraph current, yet is so intense as to destroy the receiving instruments, so that no subsequent messages can be received. In some fatal injuries the nerve that would carry the pain to the brain is destroyed, and such accidents are almost painless. Our sense of pain is greatest in the skin, and deep wounds are therefore not more painful than shallow ones. In surgical operations the skin incision is often the most painful part, and those who have been run through the body say they were conscious only of something cold passing through them, with just a prick at the points of entry and exit of the weapon. On the other hand, some fatal injuries are very painful, especially those that interfere with breathing, such as injuries to the chest and throat.—*New York Advertiser.*

Progress of Medical Science.

Tuberculosis of the Uterine Adnexa. — A. Hegar discusses the diagnosis and treatment of female genital tuberculosis ("Tuberculosis of the Fallopian Tubes and of the Pelvic Peritoneum," *Deutsche medicinische Wochenschrift*, 1897, No. 45). He distinguishes both an ascending and a descending form of tubal and pelvic peritoneal tuberculosis. In the former the bacilli are derived and introduced from the fæces of those suffering from intestinal tuberculosis, from the fingers and instruments of the doctor or midwife, or from the seminal fluid of men having tuberculous orchitis (though this last method of introduction of bacilli is very improbable). In the descending form the bacilli come from the intestines or from degenerated mesenteric glands, and thus the peritoneum is invaded: and perhaps from the now diseased peritoneum the bacilli gain access to the ostium tubæ through its fimbriated extremity. The gross changes in form and position of the tube are similar in its different inflammatory conditions. The diagnostic points for tuberculosis of the tube are nodular swelling of the isthmus tubæ and perhaps also a similar condition of the interstitial portion of the tube. If in rectal or vaginal examination one feels small nodules of the size of a pea or a bean, or even larger, on the posterior uterine surface, in Douglas' pouch, on the posterior leaf of the ligamentum latum, on the posterior portion of the lateral pelvic wall, along the sacro-iliac joint, in the paravaginal tissue, then the diagnosis of pelvic-peritoneal tuberculosis may be made; yet the physician must think of the possibility of sarcomatous and carcinomatous metastases, metastases of tubal cystomata, small fibroids, and isolated inflammatory thickenings of the serosa. In only one case could Hegar establish the diagnosis of tubal tuberculosis by microscopical examination of uterine scrapings. Of importance, as pointing to a tuberculous infection of the uterine adnexa and peritoneum, are tuberculous disease in other organs or residua of the same, and also the general nutritive disturbances similar to those observed in tuberculosis of other portions of the body. Hegar describes the effect of the local tuberculous disease upon the development and function of the neighboring organ. In three cases he found a very small and infantile uterus; two of these patients had never menstruated, though past the age of puberty. Without doubt, cases of tubal and peritoneal tuberculosis undergo a spontaneous cure fairly often, though the writer does not deny the value of laparotomy in some of these cases. He condemns laparotomy in the old and indolent forms of the disease. He advises this operation in those in whom there have been for quite a long time inflammatory processes, and in whom appropriate treatment has not bettered these inflammatory conditions. Hegar believes that an abdominal operation is always indicated, as opposed to a vaginal operation, for only by the former can the operator see the full extent of the disease and remove the tumors without tearing and crushing them or squeezing out their contents.

The Mammoth Cave of Kentucky.—The air within the cave has a uniform temperature, summer and winter, of 54° F. The cave may be said to breathe twice a year—inhaling during the winter and exhaling during the summer. This breathing of the cave, and the purity of the air and its freedom from germs, are among the most interesting problems to be studied. By what process the air in the cave becomes sterilized remains to be determined.—John R. Procter, *The Century Magazine*, March, 1898.

MEDICAL RECORD:

New York, April 16, 1898.

CARE OF THE WOUNDED IN NAVAL WARFARE.

ONE of the most difficult problems to be faced, in the event of the war, which, unless some unlooked-for change in the present state of affairs takes place, appears to be inevitable, will be the care and treatment of the wounded in and after naval battles. That the decisive fighting will occur at sea is, in the opinion of most competent military experts, a foregone conclusion, and therefore every possible effort should be put forth to provide adequate accommodation and proper treatment for those who may be wounded. The fact that a battle-ship of the modern type is, even in times of peace, sadly lacking in the necessary facilities for caring for the sick, is too well known to dwell upon, and it follows as a matter of course that these conditions will, when war is in progress, be sharply accentuated. In truth, the outlook as regards this phase of the situation is by no means pleasant to contemplate. Little is known of the effects of modern naval warfare on a large scale, but from the slight experience gained in the Chino-Japanese war it is certain that new methods of treating wounded men in action must be initiated, as well as of caring for them subsequently. In the days of wooden ships, those requiring surgical treatment were brought to the surgeon; in the modern man-of-war, divided into numerous compartments by steel decks and water-tight doors, such methods are impossible and other means of succoring those in need of assistance must be devised by the surgeons. Again, the position of the surgeon will be one of much greater personal danger than was formerly the case; he will not be able to fix upon a particular spot where he can perform his necessary duties, but must be wholly guided by circumstances and must choose a sheltered place in the ship anywhere most convenient. His equipment and the means of transporting the wounded must be of the simplest.

But the question of how most efficiently to care for the wounded after the engagement is perhaps more important than during the action itself. It will be impossible to give them the need, care, and treatment on the ship itself, and in many instances the distance from land will be too great for the services of a hospital to be available. It would appear therefore that an ambulance ship should satisfactorily supply this want. The suggestion that an ambulance ship should accompany every fleet on active service was first made by Dr. J. Rufus Tryon, formerly Surgeon-General of the Navy.

Dr. Van Reypen, the present Surgeon-General, read a paper strongly urging its adoption at the Moscow international medical congress, in which he submitted plans of such a ship. These are as follows: "The vessel as designed will be three thousand five hundred and fifty tons displacement; two hundred and seventy-five feet on the load line and three hundred feet over all; with twin screws and a speed of fourteen knots; fifty feet beam, and drawing eighteen feet: a coal capacity of four hundred and fifty tons, giving eighteen days' steaming at ten knots. The water tanks will hold nine thousand gallons. The ship will carry four steam launches and four barges, each barge arranged with a flying floor between the thwarts so as conveniently to carry twelve cots on the floor. There will be beds for two hundred and seventy-four and hammock space for eighty-six, state-rooms for eight disabled officers and cot space for twelve. The forward ward on the upper deck has been left with only one tier of berths for a ward of isolation or to accommodate more serious cases. The vessel can comfortably accommodate three hundred and thirty sick or wounded men, with sufficient berthing space for the crew of the vessel. There are quarters for four medical men, two apothecaries, and twelve nurses. . . . Near the centre of the ship on the berth deck is the operating-room, eighteen by twenty-one feet. It is well lighted by a large skylight and by air ports above the deck. . . . As soon as the action is over a launch should tow its barge alongside a vessel that has been in action, the wounded should be hoisted out and into the barge and should then steam away with all dispatch to the ambulance ship, unload its human freight, and speed away again on its mission of humanity."

The naval authorities have, it is announced, decided to act on this suggestion, and have purchased the Cromwell liner *Creole*, which is being as quickly as possible converted into a floating hospital in the Newport News shipyard. This vessel is intended to accompany the North Atlantic squadron now off Key West, and her speed will enable her to keep up with the fleet.

MR. GLADSTONE'S HEALTH.

MANY rumors have been current of late regarding the state of Mr. Gladstone's health. Some of the New York journals have gone so far as to assert positively that the aged statesman was suffering from a malignant growth somewhere at the back of the nose; the exact position and extent of the disease was not, however, stated. Unfortunately, although these assertions are not borne out by the reports published in the English medical or lay journals, it must still be confessed that they seem to bear the impress of truth. The *Lancet* in its issue of March 26th, while not committing itself to any positive statement in regard to

the disease to which Mr. Gladstone has fallen the victim, nevertheless remarks that it is in all probability something more serious than facial neuralgia. This reticence on the part of the English papers is without doubt due to respect for the feelings of Mr. Gladstone and family.

An influential English weekly contains some remarks on the subject from the pen of one of the best known and most talented British men of letters, in which the grave nature of the malady is hinted at. These eloquent words will appeal to the sympathies of the American public, and are as follows: "At a period of general sickness when the names of celebrated invalids dot the columns of the daily press, one figure stands out in bold relief as the object of universal sympathy. It has come as a shock to all classes of the community to learn that for a long time past the venerable liberal leader has been suffering continuous physical torture. The pains which were at first attributed to neuralgia are now known to have a more serious origin and to require a surgical operation before any relief can be hoped for. The great age of Mr. Gladstone—he is well on the way to ninety—must render any operation hazardous, and the situation is therefore one which cannot fail to arouse the deepest sympathy with the illustrious invalid. 'In the evening of his days,' suggests the calm sunset and the peace and rest of the twilight hour, a gentle folding of the hands, and the serene smile of one who has weathered the storms of life and come to his last moorings in the calm waters of the sweet haven of home. That when the keen eyes have grown dim, the glorious voice faint and low, and the sturdy limbs feeble, the aged frame should be racked with agony, seems a cruel satire on the theory of rewards. Mr. Gladstone himself has desired—and we can all understand his feelings in the matter—that the nature of his sufferings should not be made the theme of public discussion and newspaper comment. That is the old heroic instinct which is never lacking in the born leader of men, whether they have led in the fields of war or peace. To all emotional men sympathy is welcome, but the emotional great man never wants to be pitied. There are thousands of brave men and women who even shrink from the 'pity' of their own family circle. For this reason they frequently urge the physician, to whom everything is known, to misrepresent their malady, to make it one which will insure them loving sympathy and tender solicitude, but which will not make them objects of 'pity.'"

Compassion in his case, heroically facing as he does the inevitable, is not sought by him. It is at best nothing but the delusive anodyne for a sick spirit.

MEDICAL MEASURES OF THE RECENT NEW YORK LEGISLATURE.

Public medicine had its full quota of bills before the last legislature. Out of one hundred and fifty or more, about twenty passed both houses and reached the governor. No general laws of any importance were passed, and most of those bills now in the governor's hands are of a purely local character. The few that are general do not effect any great radical change in the existing medical laws of the State. There were, however, a number of bills of considerable interest and significance which failed to pass, many of which will come up again next year in the same or in modified form.

The dispensary bill, which was vetoed last year by the governor, passed the senate by a vote of forty to two, but was pigeonholed in the assembly committee on public health in spite of the strong attempt made to get it out. The defeat of the bill was not due to any lack of hard work on the part of its adherents, but rather to powerful and well-organized opposition. There was little doubt of its passage in the assembly had it been reported by the committee. The first attempt in this State to regulate medical expert testimony was represented by a bill, fathered by the State Homœopathic Medical Society; but it was not heard of after reaching the committee. The first attempt to legalize osteopathy in New York State was likewise buried by the committee. The medical press was up and against it, as it is against all such chicanery, almost before it saw light. The Montgomery County midwifery bill, noticed in a recent issue of the Medical Record, passed both houses and is now in the hands of the governor. There were several hearings and the opponents of the measure took the stand that local laws of this character were objectionable and that next year a general law would be introduced controlling the practice of midwifery throughout the State. The lively discussion indicated that the introduction of such a bill would, without doubt, precipitate a fight, notwithstanding the need of a general law controlling the practice of midwifery. The several bills placing barber shops under control died in committee. The "short-hour drug-clerk bill" applying to Greater New York, after numerous hearings and considerable opposition, passed both houses. The bill providing for the inspection of cold-storage warehouses by boards of health in cities of the first class was reported out of the assembly committee, but failed to obtain a place on the calendar, and the bill forbidding the sale of goods in second-hand packages did not get out of committee. The Greater New York health-board bill introduced by Dr. Brush in the senate and Mr. Laimbeer in the assembly was held in committee in both houses. On the senate side several hearings were given, and the original bill was amended, but it was not reported. The resolution in the senate concerning the State colony for consumptives died in the committee on finance. The resolution provided for the appropriation of $1,000 for the preliminary work in establishing this charity. Craig Colony received $158,000, Dannemora State Hospital for Insane Convicts $77,252.

It is not difficult to see that no great progress has been made in any one line of reform or improvement which is general in application.

Individual Communion Cups.—Asserting that the common use of one cup in communion services is a menace to health, the Indiana State board of health has recently recommended the use of individual cups.

PURE WATER FOR TROOPS ON ACTIVE SERVICE.

Now that there seems to be a likelihood of our soldiers engaging in warfare, and in a country too notoriously unhealthy for unacclimatized white men, every regard to the sanitary arrangements of the army should be carefully looked into, and especially so far as a pure water supply is concerned. The prevalence of fever, and the amount of field service performed by the troops, has several times been pointed out as a well-marked coincidence. The reason of this is not far to seek, but must in the large majority of cases be put down to the impurity of the water which the men on active service are compelled to drink. Attention was drawn to this matter in the MEDICAL RECORD of a recent date. This danger of contracting fever from this cause might be greatly lessened by providing portable water filters for troops operating in the field. At such times the men are dependent upon surface-water supplies, and it may be said that surface-water supplies are always dangerous. Dr. Smart, in a communication to the office of the war department in July last, discussed this subject and in the course of his remarks said: "I desire to point out that in the early days of the settlement of our Western country fevers were common, both in military commands and in civilian communities. These fevers were of an adynamic type. By some observers they were regarded as malarial remittents, by others as specific typhoid fevers, while others again, among whom was myself, considered that although the majority of the cases were of malarial origin, occasional cases were due to the specific cause of enteric fever, either developed *de novo* or propagated from some previous cause. Notwithstanding differences of opinion as to the nature of the fevers, there was a general belief that the water supply was concerned in their causation. This belief became strengthened as continued observation showed that these fevers diminished in prevalence both at military stations and in civilian settlements as purer water supplies were obtained. The advisability of providing pure water for troops in the field may be considered evident. The possibility of making this provision seems to have been hitherto an untried experiment, at least in this country." It is impossible to gainsay the truth of these words, and at this juncture they should have special weight, for in the case of hostilities being carried into Cuba, it is more than probable that those engaged in fighting would have as much to fear from disease as from Spanish bullets. Therefore it will be judicious to take every possible precaution.

Chicago Women in the War.—The Medical Women's Club of Chicago, at a recent meeting, appointed a committee to raise a corps of women physicians and nurses in case of a war with Spain. It is thought that from twenty to thirty physicians and five hundred or more nurses will be ready to tender their services to the government whenever they may be needed.

News of the Week.

Dispensary Abuse in Boston.—The Boston Medical Society has addressed an open letter, dealing with the vexed question of medical charity abuse, to "the trustees, the superintendents, the staffs, and the medical officers of the hospitals and dispensaries of Boston." In this letter the writers say that they have no complaint to make concerning the ethics of the persons addressed in their private consultations with general practitioners, but "as private practitioners," they continue, "we have had, with no slight feelings of regret, occasion to experience what seems to us an entirely different condition of things, as manifested in the methods which are employed by some of the medical men who are connected with the medical and surgical out-patient departments, in the several large dispensaries, in their relations to us as professional brethren, and in their relations to certain dispensary patients, especially to those patients who were ours perhaps a day, or an hour, or a year, previously, and who would otherwise be ours continuously, when occasions require, if only the same principles of medical ethics were carried out by these gentlemen in public practice as they would undoubtedly carry out in their relations to us in private practice. . . . As to medical consultations in general, aside from the special welfare of the patients, two things are always of particular importance, as between the practitioner and the consultant, namely: first, that the former shall remain in full charge of the patient, and second, that he shall have his standing with his patient enhanced and fortified. Therefore, that this is not done in our large dispensaries, is precisely what we allege against certain medical men and medical officials, who practically have charge of the conduct of all the principal dispensaries in Boston. . . . Ethically, as well as justly, it certainly cannot be held by any physicians, nor should the public be led to believe by any words or acts on the part of medical officials or dispensary practitioners, that private practitioners in general, who are instructed by these same professors, who are graduated from the same colleges, who possess the works of the same authorities, who employ the same therapeutics, who proceed upon the same theories, who have as good a practical experience, who realize as great a sense of responsibility, and who evidently are inspired by as high an ethical sense, are less competent professionally or less successful with given cases than many of those physicians and surgeons who are officially connected with the dispensaries and with the out-patient departments of the hospitals." Evidently, Boston is very much like the rest of the world, at least as far as real wickedness goes.

German Medical Professors in Constantinople.—The Turkish government having asked for a professor of medicine from Germany, the Emperor has granted the necessary authorization to Dr. Rieder of the University of Bonn. The newly-appointed professor is to receive 30,000 francs ($6,000) a year. He will also have an assistant, who is likewise a German. The

latter is to have a salary of 15,000 francs ($3,000) a year. Dr. Rieder is charged with the reorganization of the medical school. Besides their services at the school these gentlemen will also inspect the military hospitals of the city.—*The Lancet.*

Action of the Saginaw County (Mich.) Medical Society in a Case of Plagiarism.—At a regular meeting of the Saginaw County Medical Society, March 28, 1898, the committee appointed to investigate the charges preferred against W. S. Connery, M.D., reported as follows:

"*S. C. J. Ostrom, M.D., President, Saginaw County Medical Society.*

"SIR: The committee appointed by you in accordance with a resolution of the above-named society, adopted on March 11, 1898, the duties of such committee being to investigate and report on charges preferred against W. S. Connery, M.D., a member of said society, beg leave to report that after notifying the said W. S. Connery, M.D., of their appointment, time, and place of meeting, and requesting him to appear before your committee and make answer to said charges, he has failed to answer either by presence or by letter.

"After reading the article published in the New York MEDICAL RECORD, of date January 8, 1898, also the apology for publishing the same made by the editor of the MEDICAL RECORD in its issue of February 26, 1898, to Sir William Broadbent, the author of said article on 'Angina Pectoris,' published in the MEDICAL RECORD of January 8, 1898, by the said W. S. Connery, M.D., as his own original work, and said by him to have been read before the Saginaw County Medical Society by the said W. S. Connery, M.D., we can come to no other conclusion than this, viz.: That the said W. S. Connery, M.D., is guilty of plagiarism in publishing as his own production the said article on 'Angina Pectoris'; also guilty of misrepresentation in saying that this paper was read before the Saginaw County Medical Society when it had not been so read before the society; also in claiming that he was at that time president of the Saginaw County Medical Society, which he was not at the time the said article on 'Angina Pectoris' was published in the MEDICAL RECORD, viz., on January 8, 1898. He was thereby guilty of falsehood and misrepresentation, and conduct unprofessional and ungentlemanly and prejudicial to the best interest and reputation of the Saginaw County Medical Society, of which he is now a member; also his nonappearance before your committee would seem to be a confession of the truth of the charges preferred against him, and we, your committee, believe him guilty as charged.

[Signed] "SAMUEL KITCHEN, M.D., EUGENE W. DAVIS, M.D., T. M. WILLIAMSON, M.D., *Committee.*

"SAGINAW, MICH., March 24, 1898."

Upon motion the above report was received and adopted and the committee discharged. It was moved by Eugene W. Davis, M.D., and seconded by J. W. McMeekin, M.D., that W. S. Connery, M.D., be and is hereby expelled from membership in the Saginaw County Medical Society for unprofessional conduct, and that a copy of the above report and the action of the society thereon be furnished the New York MEDICAL RECORD, the *Medical Age* of Detroit, Mich., and the *Physician and Surgeon* of Ann Arbor, Mich., for publication. The motion was carried by a unanimous vote.

MORRIS C. L. KITCHEN, M.D., *Secretary, Saginaw County Medical Society.*

S. C. J. OSTROM, M.D., *President, Saginaw County Medical Society.*

Obituary Notes.—DR. JOSEPH F. COLGAN died on April 8th, at his home in Brooklyn. He was born in Brooklyn thirty-three years ago and was graduated from the Long Island College in 1890. He was the last of six generations of physicians. For several years past he had been a medical examiner for the Pension Bureau.—DR. JOHN D. VAN SAUN died suddenly in Jersey City, on April 9th. He was born in Jersey City thirty-eight years ago, and was graduated from the Bellevue Hospital Medical College in 1873. He retired from practice two years ago because of failing health.

Dissensions in the Faculty of the University Medical College.—For some time rumors have been current concerning a split in the medical faculty of the New York University, and within a few days the trouble has followed the course of most family quarrels and is being aired in the daily papers. The difficulty is understood to have arisen over the transfer by the Medical School to the university council of the college buildings on East Twenty-sixth Street, the agreement entered into at the time being said not to have been carried out by the council. There is said to be good ground for the assertion that several members of the faculty will refuse to serve at the close of the present session, and that plans are being formed for a new medical school in this city, to be conducted under the auspices of Cornell University. The New York University Medical College was organized in 1837, and opened in 1841, in the old Stuyvesant Institute, at Broadway and Bond street, afterward moving to East Fourteenth street, where its buildings were burned. It then moved to Broadway and Duane, and in 1869 settled in East Twenty-sixth Street, where it now is.

A Wholesale Experiment in Yellow-Fever Prevention.—It has been reported that the army medical authorities, have prepared a large supply of yellow-fever antitoxin, and that all the unacclimated troops sent to Havana and other parts of Cuba, in case of war with Spain, will be inoculated by way of prophylaxis, and also that a thorough test of the curative properties of the serum will be made in all cases originating in the island.

The Late Amos R. Eno left by will the sum of $5,000 to each of the following institutions in this city: Colored Orphan Asylum, Demilt Dispensary, Protestant Half-Orphan Asylum, Association for the Relief of Respectable Aged and Indigent Females, Home for Old Men and Aged Couples, New York Cancer Hospital, Society for the Relief of Ruptured and Crippled, New York Training-School for Nurses, and the Institution for the Blind.

Reviews and Notices.

Outlines of the Diseases of Women. By John Phillips, M.A., M.D. Cantab., F.R.C.P., Assistant Obstetric Physician to Kings College Hospital, etc. With 130 illustrations and two appendices. Second edition, revised. Pp. xvi. + 275. London: Charles Griffin & Co. 1897.

The present edition has been somewhat enlarged by the addition of a few paragraphs, especially the one on movable kidney. On account of the ground covered, the book is essentially a larger quiz-compend, which is rendered more valuable than most works of this class by reason of the list of references that follows each chapter.

The author keeps constantly in mind the needs of the student, so that many of the descriptions may seem elementary to the practitioner. In spite of their brevity the descriptions of operations are quite satisfactory. The sections on treatment are conservative, the writer believing that gynæcology is not absolutely synonymous with surgery. The diagrams explaining the extension of malignant disease of the uterus, displacements, etc., are especially helpful. In general it may be stated that the student will find the "outlines" a safe and valuable guide, especially in preparing for examination.

Diseases of Women. A Text-Book for Students and Practitioners. By J. C. Webster, B.A., M.D. Ed., F.R.C.P. Ed.; Demonstrator of Gynæcology, McGill University; Assistant Gynæcologist, Royal Victoria Hospital, Montreal, etc. Illustrated with 241 figures. Pp. xxii. + 688. Edinburgh and London: Young J. Pentland. New York: The Macmillan Company. 1898.

This compact little manual presents several features of excellence. Prominence is given to anatomy, especially to the pelvic floor. Chapter VI., on "The Genital Tract in Relation to Micro-Organisms," is novel and interesting. Chapter IX., dealing with surgical technique, is condensed but quite exhaustive. The sections on pelvic inflammation and on hæmatocele are rather conventional and will meet with criticisms from modern pathologists. We are sorry to see the expression "chronic inflammation" used in reference to conditions which are rather the results of acute inflammation. We note with approval the chapters on uterine neoplasms, though it would seem as if undue prominence was given to the rare condition deciduoma malignum. Operations are described briefly but lucidly.

Twenty-five pages on the theory of menstruation are included in the appendix, and will be read with interest.

The book is most pleasing in its general appearance, the type, illustrations, and binding being entirely satisfactory. The author's clear and common-sense exposition of his subject marks him as an experienced clinical teacher.

A Laboratory Manual of Medical Chemistry. By Ira Carleton Chase, A.M., Professor of Chemistry and Toxicology in the Medical Department and Professor of Analytical Chemistry in the Scientific Department of Fort Worth University, Fort Worth, Texas. 1898.

The present small volume is, like many others of its class, a systematic arrangement of lecture notes upon medical chemistry. It deals with laboratory manipulation and the general theory of chemical action, the more important non-metallic elements, the general chemical properties of the principal metals used in medicine, water analysis, medicinal organic compounds, the chemistry of the fluids of digestion, of the blood, and of milk, urine analysis, and toxicology of the common irritant and neurotic poisons.

While the general plan of this compendium is excellent, it is, we believe, open to criticism, in that it attempts to do too much and is quite inconsistent in its method of treatment; thus the student who is competent to do good gravimetric and volumetric work, which is called for in the chapters on water analysis, would be one who had done all the earlier work in the book a year or so previously, in a regular chemical course. Again, it seems to be a mistake to sandwich organic chemistry with inorganic in miscellaneous confusion. The medical student should have run his course in inorganic chemistry and physics before entering a medical college, and when there should devote his chemical time to work along purely physiological lines. The book, while exact and well executed, and in certain respects commendable, is too much of a primer hodge-podge of the cookery-book order.

Report of Hôpital Saint-Jean, Bruxelles. Service Chirurgical du Dr. A. Gallet, Année 1896. Brussels, 1897.

If one were to seek the driest and most unprofitable type of medical reading, one would turn to the hospital reports and the reports of boards of health. In this country, at least, such publications are for the most part wearisome and useless pages of figures. In the case of hospital reports they consist of detailed and specific lists of so many dozen night shirts, turkeys, and cups and saucers donated by good Samaritans whose left hands otherwise would not know what their right hands had done.

It is refreshing to receive a report in which the statistics of such trifling value are reduced to a minimum, and in which the pages are devoted to careful and detailed scientific study of cases occurring in the service. The observations in this report cover a wide range of surgical activity—traumatic shock, brain surgery, pylorectomy with Murphy buttons, nephropexy, appendicitis, hysterectomy, cœliotomy, costa resection, pyæmia, surgery of the kidney, and various studies of malignant tumors. The studies are to be commended as a type of work which, if carried on by all large hospitals, as is being done by a few, would render their reports of value to physicians rather than to junk men.

Zur Thätigkeit der cellulären Körperelemente bei Infectionskrankheiten. Von Dr. Bruno Schurmayer. Berlin: O. Coblentz. 1897.

In a small brochure of thirty-one pages the author discusses in a pleasing and clear manner the various theories of immunity, and sketches rapidly the various steps in the development of the purely morphological ideas of Metschnikoff and his school and the chemical theories of the German schools. He shows clearly that too strict an adherence to either theory is liable to lead to false interpretations, and that, although the chemical point of view is the more important, one must bear in mind both the morphological and chemical accompaniments in the complex biological processes of disease and immunity.

Ricoerche sull' Anatomia Normale e Patologica delle Terminazioni Nervose nei Muscoli Striati. By L. T. Cipollone. Rome. 1897.

The investigation of the endings of the nerve fibres in the striated muscles has been a subject of careful investigation for a number of years. Recently the importance of these investigations has been more firmly established in the study of the muscular dystrophies and muscular atrophies. The present study is a noteworthy addition to our literature upon this branch. The author studies the normal nerve endings in the lizard, pigeon, frog, guinea-pig, rabbit, dog, and man. He discusses fully the various methods of technique and the changes due to trauma of various nerves. The paper is well illustrated, and is a careful and full treatment of the whole subject.

Grundriss der klinischen Bakteriologie. Für Aerzte und Studirende. Von Dr. Ernst Levy und Dr. Felix Klemperer, Professor und Privatdocent an der Universitat zu Strassburg. Zweite vermehrte und verbesserte Auflage. Berlin: A. Hirschwald. 1898.

Bacteriological manuals are of various kinds and occupy different fields in science. Works such as Flügge's "Mikro-Organismen" cover the entire field, but such have proven of service to the investigator and teacher rather than to the student. The present volume confines its attention more particularly to the clinical aspects of bacteriology, and is therefore particularly of value to the working doctor rather than to the laboratory bacteriologist.

While the methods of cultivation and the morphological characters of the various species of bacteria are discussed and the biological characters indicated, it is to the presence of the organisms in different diseases, the methods of detecting the same, and their manner of working in the tissues, with the symptomatic results, that the authors specially devote their attention.

The book is divided into four parts, dealing respectively with general bacteriology, inflammation and pus formation, specific bacterial diseases, infection with other forms of life, vegetable and animal, with an appendix on methods of ex-

amination of water, air, and ice, disinfection, etc. It is carefully written and is distinctly practical.

MANUAL OF GYNÆCOLOGY. By HENRY T. BYFORD, M.D., Professor of Gynæcology and Clinical Gynæcology in the College of Physicians and Surgeons of Chicago, Professor of Clinical Gynæcology in the Woman's Medical School of Northwestern University, Professor of Gynæcology in the Postgraduate School of Chicago. Second Edition, containing 341 illustrations, many of which are original. Pp. xxiii. + 596. Philadelphia: P. Blakiston, Son & Co. 1897.

WE have already had occasion to refer to the many excellent features of this work, and need hardly add that the present edition is a marked improvement over its predecessor. Many new pages have been added, and several chapters have been rewritten. We commend especially the chapters on gynæcological technique and anatomy, and the description of operations, the latter being terse, but vivid, and most helpful to the student. The system of marginal notes is another commendable feature of the new edition.

The sections devoted to malignant disease are properly illustrated and compare most favorably with the corresponding chapters in other text-books. The concluding pages on extra-uterine pregnancy bear the marks of careful revision.

In its present form this manual reflects great credit upon the excellent clinical teacher whose name appears upon the title page.

ENCYKLOPÄDIE DER THERAPIE. Herausgegeben von OSCAR LIEBREICH. Zweiter Band, 11, 2. Berlin: August Hirschwald. 1898.

THE continuation of this valuable encyclopædia maintains the high standard promised by the earlier numbers. The present Lieferung includes subjects of therapeutical interest from "Glucose" to "Hydronephrosis." The several topics are treated in a terse and brief manner, yet the facts are interpreted in accordance with the best and latest methods. When completed this encyclopædia will make an excellent work for rapid consultation.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 7, 1898.

EGBERT H. GRANDIN, M.D., VICE-PRESIDENT, IN THE CHAIR.

Final Report of Semi-Centennial Committee.—DR. EDWARD D. FISHER reported that the receipts for this celebration amounted to $3,329, and that there was a balance at present of $661.78.

Semi-Centennial Library Fund.—On motion of DR. W. M. POLK, five hundred dollars of this balance was set aside as a nucleus for a "semi-centennial library fund," and the rest was appropriated to defray the expense of publishing the addresses delivered at the semi-centennial celebration in the academy's volume of transactions.

Vote of Thanks to Ex-President Cleveland.—On motion of Dr. Polk, the secretary was instructed to transmit the thanks of the academy to Grover Cleveland, ex-President of the United States, for his kindness, not only in attending the semi-centennial exercises, but in presenting to the academy an autograph copy of his address.

Vote of Thanks for the Gift of the New York Hospital Library.—On motion of Dr. Polk, the academy sent a vote of thanks to the governors of the New York Hospital for the donation of their library to the Academy of Medicine. In doing so, he explained that many applications had been made to the governors for this library, and it had been suggested to make it a part of the new library of the city of New York, but that Dr. Billings had unhesitatingly expressed the opinion that the proper place for it was in the Academy of Medicine.

Uterine Fibroids.—This was the special theme selected by the section on obstetrics and gynæcology for discussion before the academy at this meeting.

Their Pathology.—DR. GEORGE C. FREEBORN discussed this part of the subject. He said that these tumors were composed of connective tissue and smooth muscle mingled in varying proportions. Clinically they might be classified as hard and soft fibroids. These tumors were usually of slow growth. Another division was into subserous, submucous, and interstitial fibroids. All fibroids, not pedunculated, were to be considered as subserous. During the growth of the tumor it might be pushed into the broad ligament, forming what was known as an intraligamentous fibroid. A submucous fibroid was a tumor which was separated almost entirely from the uterine wall, and which hung free in the cavity of the uterus. They were usually of rapid growth. The largest number of fibroids recorded as having been found in one uterus is fifty, and the largest fibroid, in point of size, was one reported by Dr. Hunter, which weighed one hundred and forty pounds. The common change taking place in the wall of a uterus in which a fibroid was growing was hyperplasia, and it was most marked in connection with interstitial and submucous fibroids. The fibroid tumor itself might undergo certain changes. Important among these was atrophy. They might also undergo calcification. It was most common in the submucous variety. Complete calcification resulted in a cessation of growth. Myxomatous degeneration occurred in both interstitial and submucous fibroids of large size. It was confined at first to one or more circumscribed areas, and resulted in the formation of cysts. Fibroids might also undergo suppuration. Carcinoma and sarcoma were found in uterine fibroids, and were generally spoken of as "malignant degeneration," which was a misnomer, for they were really new growths. In the adeno-myomata there were elements from which it was possible for a carcinoma to originate.

Fibroids Complicating Pregnancy.—DR. HENRY C. COE presented a communication on this subject which, in his absence, was read by Dr. Tucker. He stated that there was still considerable diversity of opinion regarding the significance of the occurrence of pregnancy in a fibro-myomatous uterus. It was true that conception was comparatively uncommon in such uteri, but it was well known that the subserous growths so commonly found in the negro race did not prevent conception. When there was a continued increase in the growth of the tumor, or hemorrhage, or urgent pressure symptoms, operative interference was indicated. A subserous growth at the fundus might cause retroflexion and incarceration of the growth. Among the internal changes which might take place in the neoplasm itself in consequence of obstructed circulation from pressure, were hemorrhage, cystic degeneration, and even necrosis. Small interstitial growths often remained quiescent. Interstitial or subserous growths situated in the true pelvis might give rise to disturbances entirely out of proportion to their size, and demanded operation. Sloughing of intrauterine polypi was always to be apprehended if pregnancy occurred. With large interstitial fibroids the placenta was apt to become prematurely detached, giving rise to early hemorrhage. An opinion having considerable support was, that although a fibroid might enlarge under the stimulus of pregnancy, it would undergo atrophy and disappear during the involution of the uterus after parturition. A certain amount of atrophy certainly might occur, but one would hardly recommend pregnancy as a cure for fibroids. In making the diagnosis it was often advisable to make an examination under general anæsthesia. In the treatment, the physician could not be guided by any fixed rules, but each case called for the exercise of the ripest judgment. A pedunculated fibroid would usually

bear careful watching, because of the liability to torsion of the pedicle. Pregnancy might often go on to full term with impacted tumors in the pelvis, but it was highly probable that the child would be born dead, and the mother would be exposed to great risks. Myomectomy by the upper route might be attempted under favorable conditions, with a fair prospect of success. In a doubtful case it might be better to perform cœliotomy at once, so as to determine the exact conditions of the growth. The abdominal was certainly preferable to the vaginal route. Submucous polypi might be removed in the ordinary manner when accessible, while subperitoneal growths might be disregarded unless they were pedunculated, or the pedicle underwent torsion. When the tumor became impacted, if its liberation under anæsthesia was impossible, the abdomen should be opened. They might be left alone if they rose out of the pelvis with the uterus; if not, abortion should be induced. If there was any reasonable doubt, explorative cœliotomy was perfectly justifiable. If the tumor was not discovered until the latter half of pregnancy, in the absence of serious pressure symptoms it was better to wait until near full term, and then perform Cæsarean section with supravaginal amputation of the cervix, subject, of course, to the wishes of the patient.

Surgical Treatment of Fibroids.—Dr. William M. Polk discussed this phase of the subject. He confined his remarks to the consideration of hysterectomy and myomectomy, expressing the belief that the latter would prove to be the operation of the future. As to the conditions demanding the vaginal operation, he said that no tumor greater in size than a uterus at the fourth month of pregnancy should be removed by this method, and there should be a reasonable assurance that there was no associated suppurative disease of the appendages. Another complicating condition, though a rare one, was malignant disease. He was of the opinion that all such tumors were best removed by the abdominal route. In operating by the vaginal route, the average operator required a rather roomy pelvis. While in general terms the normal type of pelvis was the only one permitting the vaginal operation, it should be remembered that even with a roomy pelvis the operation was contraindicated if the vagina was small. It was important, he said, when operating, to properly control the hemorrhage from the very vascular parts. For this purpose a very free incision was necessary. He preferred to leave the ovaries, when these organs were healthy, on account of their effect on the general health in the way of preventing unpleasant nervous phenomena. After ligating the ovarian arteries, and clamping the tissues close to the uterus, the assistant grasped the tumor below the clamps and lifted it out of the pelvis, thus giving the operator an opportunity to further control the vessels. All the tumor was to be cut away above the clamps, and then the vessels were isolated and ligated. His own preference was to remove the cervix, although it caused more hemorrhage. In closure of the peritoneum the stump of the ovarian vessels should be left within the cavity of the peritoneum, and not turned into the subperitoneal space along with the ligated stump of the uterus. He laid stress upon the importance of isolating the uterine artery before ligation.

Myomectomy.—He believed that in some cases myomectomy was imperative; for example, cases of submucous fibroids. Every case that could be treated by myomectomy should be operated upon in this way, remembering that the mortality depended largely upon the drainage, and the strictest precautions against infection should be taken.

The Origin of Fibroids.—Dr. H. J. Boldt opened the general discussion. He said that Dr. Freeborn had failed to touch upon the question of the origin of fibroids. His own view had long been that they arose from the muscular structure of the smaller blood-vessels. The study of this subject was, of course, only possible in exceedingly small fibromata. Regarding the sources of infection giving rise to suppuration in fibromata, he said that it seemed to him very doubtful that such infection had its origin in the bladder or in the bowel. His own experience had been that infection usually arose from some form of intrauterine traumatism, as from the use of the uterine sound, or the curette, or from attempts at abortion. In dealing with fibroids complicating pregnancy, it should be remembered that the great majority aborted between the second and fifth months. The cause of this was probably the same as that which usually prevented the occurrence of conception in cases having fibroids, *i.e.*, the inflammation of the endometrium. If, however, the pregnancy went on to term, he believed the tumor, if pedunculated, could usually be dislodged under anæsthesia. He did not think it was warrantable to persevere in prolonged attempts at delivery *per vias naturales*; it was far safer to perform Cæsarean section than to effect delivery by a craniotomy or other severe obstetric operation. If the fibroids were of the interstitial variety, there was great liability of suppuration or gangrene occurring, and this being the case it was the duty of the physician to proceed immediately to the removal of the uterus and neoplasm. Regarding the method of operating, he expressed himself as thoroughly in favor of the total operation, for he did not believe the Porro operation was destined to remain an accepted operation in this class of cases. Dr. Coe advised against matrimony for women having a uterine myoma. This seemed to him a rather extreme position, for comparatively few of them conceived. At the present time it was considered that hysterectomy was not more serious than an ovariotomy. The vaginal operation should be limited to a tumor not larger than a uterus at the fourth month of pregnancy. Even though the vagina were small, he would not hesitate to operate by cutting the vagina to gain more room. Convalescence in such cases was rather more tedious, but the operation seemed to be safe. He would not, however, operate by the vaginal route if the pelvis were of the male type. Undoubtedly myomectomy was not done sufficiently often, and was destined to be the operation of the future. In two cases in which he had left the cervical stump when removing the uterus, there had been an exudate. This had not occurred in the cases in which he had done the total extirpation. His plan was first to place the clamps alongside of the uterus, and then cut close to the uterus down to the base. The myoma was next enucleated on either side. He had not left the ovaries behind, and did not think there was any advantage in so doing. In order to control the hemorrhage after cutting the broad ligament, the vessels could be readily ligated separately under the guidance of the eye. For this purpose No. 1 or No. 2 catgut was used. The broad ligament was then sewed with fine sutures so as thoroughly to close in the wound.

The Operation of Partial Extirpation.—Dr. J. Riddle Goffe said that he was especially interested in the technique for the removal of fibroid tumors. On general principles he was strongly in favor of preserving intact the ovaries and tubes, and so keeping up the menstrual influence. However, a recent experience in this line of conservative surgery had led him to pause, because it had been necessary subsequently to remove these organs, although at the first operation they had appeared to be free from disease. He was an advocate of leaving the stump of the cervix, not only because this method of operating took less time, but because convalescence was perfectly smooth, and the parts were restored after the operation nearly to their normal condition. Convalescence was

not disturbed by changing dressings. His plan of operating for the removal of the uterus in cases of fibroid tumor was to pass a ligature under the ovarian artery, and ligating over the border of the broad ligament. He preferred to use a long ligature of No. 8 catgut, and to include the different vessels in successive loops of this ligature. An anterior and posterior flap of peritoneum was dissected up beyond the uterine arteries, and a part of the long ligature was passed underneath these flaps. On drawing this ligature taut, the broad ligament was puckered up and covered with the peritoneal flaps. The upper portion of the uterus was then removed, after which the peritoneal flaps were reversed. Before closing the wound, it was his custom to apply pure carbolic acid to the interior of the cervical canal. He had been doing this operation for ten years, and the results had been better than by all other methods.

Favors Total Extirpation.—Dr. H. N. Vineberg said that last summer a woman of twenty-two years had consulted him. She had well-developed ovaries but a rudimentary uterus, and was greatly troubled by the menstrual molimina. These symptoms disappeared promptly on the removal of the ovaries. Such an experience led him to doubt the wisdom of removing the uterus and leaving the ovaries intact. Every time he had performed hysterectomy and had left the cervix behind he had had occasion to regret it, and in one instance he felt that it had been responsible for the death of the patient. He would admit that a great deal of experience with this method was necessary in order to carry it out successfully. It seemed to him that whenever one found a small fibroid which was easily removable from the vagina, it was proper to advise its removal even though it gave rise to no symptoms. This might seem to some too radical, but he thought it would avoid in many instances serious consequences. He had operated five times by ligation of the uterine arteries. Only the last case had proved successful, but in this one the cure had been complete and most satisfactory.

SECTION ON SURGERY.

Stated Meeting, March 14, 1898.

W. W. Van Arsdale, M.D., Chairman.

Acute Strangulated Omental Hernia.—Dr. W. B. Coley presented a case of acute strangulated omental hernia of the interstitial variety, illustrating a very rare condition. On February 23, 1898, the patient, a man of thirty years, was dancing, when he felt a sudden and severe pain in the left inguinal region, and coincident with this a swelling appeared here. This was accompanied by nausea and some vomiting. When seen on February 24th, about twelve hours afterward, he walked with difficulty and with pain, and there was an elliptical tumor extending from the scrotum over the inguinal canal, and about three inches beyond the external ring, overlying the aponeurosis of the external oblique. The tumor was clearly cystic, but so tense that the exact nature of its contents could not be determined. The bowels had moved slightly that morning. In view of the cessation of the acute symptoms and the general condition, the diagnosis of acute strangulated omental hernia was made. The operation was performed the next morning, and the diagnosis confirmed. Six or eight ounces of serum was present, together with a large mass of congested omentum. The constriction was formed principally by the neck of the sac, and a second constriction higher up was formed by the ring. Between the external and internal rings was a dilatation of the sac. The whole canal was slit up freely; the sac was tied off on a level with the peritoneal cavity, and, the sac being congenital, it was tied over the testicle and the entire wound closed by the Bassini method. The wound healed by primary union. The speaker said that acute strangulation of the omentum was very rare. In this case there was undoubtedly a congenital sac, which was almost entirely obliterated in the upper portion.

Delayed Union Following Fracture of Both Bones of Forearm; Numerous Operations.—Dr. I. S. Haynes presented a man, forty-four years of age, a painter by occupation, who, on August 6, 1895, fell from a scaffold, a distance of thirty feet, fracturing the sixth, seventh, and eighth ribs near the sternum, and also the forearm. When he was seen some time afterward by Dr. Haynes, there was some swelling about the seat of fracture, due to the callus, and the hand and fingers were the seat of bad adhesions. Under ether these adhesions were ruptured, and the ends of the bones actively rubbed together. The arm was then put up in short side splints. Later it became necessary to cut down upon the fracture, as there was still no union. Inspection showed the end of the lower fragment atrophied and rounded off. There was a little fibrous tissue between the fragments. The periosteum was peeled off and a small portion of the ends of the bone removed. The same condition was found in the ulna as in the radius, and the ends of both bones were refreshed in the way mentioned and the ulna was wired. This was in November. In January it became necessary again to operate. In December a third operation was attempted, as there was still no effort at union. The fragments were bevelled by a saw, and the bones were brought together and overlapped for a distance of about one and one-fourth inches. The fragments were then firmly bound together with silver wire. On May 1, 1897, it was noted that there was solid bony union between the fragments, but there was a small sinus still open. At present there is shortening of two and seven-eighths inches; pronation and supination are about two-thirds of the normal; the wrist and finger movements are good, although not quite normal; the arm is strong and can be used for quite heavy work.

Dr. H. Lilienthal said that, in connection with the case presented by Dr. Haynes, he would like to show an *x*-ray photograph of a very similar one. The patient was a woman, forty-eight years of age, who had broken the right arm. The fracture was at first put up in plaster of Paris, but there was no union after four weeks. The ends of the bones were ground together, and put up for another four weeks. This process was repeated, but even at the end of nine weeks there was no union. The patient then, of her own accord, had an *x*-ray photograph taken, and came under his observation. This showed not only non-union, but misplacement of the fragments. Under ether he endeavored to replace the bones, and then ground their ends together. The result was no better. He had, therefore, resected the ends of the fragments with a saw, and tied the fragments together, not by drilling, but by tying them together with silkworm gut. No callus was found at the operation, and there was no atrophy, but there were some fibrous tissue about the ends of the fragments and a true synarthrosis between the ends of the radius, with a sort of synovial fluid. After about six weeks the ulna united firmly, but the radius was still ununited.

Dr. Haynes thought the reason that union had not occurred until the bones had been overlapped was that there was a slight gaping, and the vitality was so low that this interval was not filled up by healthy granulations. In regard to the treatment of these cases, he desired to say that it was objectionable to extend the straight splints below the wrist. Immobil-

ization could be secured without so extending the splints, and the use of the long splints was liable to be followed by stiffness of the fingers and at the wrist.

Use of an Ivory Peg.—Dr. W. W. Van Arsdale said that the most common cases of delayed union after fracture seemed to be those in the tibia. In one case of delayed union in the forearm, occurring in a boy, he had tried "Thiersch's spindle," made of ivory. After thorough sterilization it was inserted into the cavity of the bone, and healing seemed to be very satisfactory. After some weeks there was some local irritation, and the spindle was consequently removed. It was found to have become eroded and reduced very considerably in size. The boy was then lost sight of for several months, but when he again came under observation it was found that firm union had taken place. It was probable, therefore, that the spindle had benefited the case.

Dr. R. F. Weir said that he could recall only three instances in which there had been non-union in fractures of the forearm. In two of these he had been able by operative procedures to secure union.

Syphilitic (?) Disease of the Fibula.—Dr. Reginald H. Sayre presented a little boy whom he had first seen about three weeks ago. About one year before the boy had fallen and injured the leg. He complained of pain along the fibula and in the thigh. The speaker had brought him to ascertain whether or not the case was one of sarcoma of the fibula. There was no definite specific history, but from the fact that improvement had followed mixed treatment he was inclined to think that the case was one of syphilitic disease. An *x*-ray photograph showed involvement of both the femur and the fibula, though nothing abnormal could be detected about the femur on palpation. This seemed to him to confirm the opinion that the case was one due to syphilis.

Probably a Sarcoma.—Dr. Coley said that, in view of the history of traumatism and the character of the swelling, it seemed to him not at all improbable that the disease was really sarcoma. It should be remembered that syphilitic disease in this region and of this form was quite rare. It seemed to him justifiable to cut down upon the part and remove a portion for minute examination.

Dr. Sayre said that, from the fact that there was slight enlargement of two joints in the body, that the femur as well as the fibula was enlarged, and that both these bones presented an abnormal appearance in the *x*-ray photograph, he was inclined to doubt the original diagnosis of sarcoma. Since the patient had been put on mixed treatment there had been evident improvement, and, therefore, the speaker felt justified in continuing this line, for the present at least. Under other circumstances he would be willing to remove a portion for examination. According to the *x*-ray photograph, if the case was one of sarcoma an amputation at the hip-joint would be required.

Malignant Disease Improved by Antisyphilitic Treatment.—Dr. Coley said that about two years ago a woman had been admitted to the Cancer Hospital with the diagnosis of specific disease of the breast. She was put upon mixed treatment, and improved so rapidly that the diagnosis seemed to be confirmed. Before she left the hospital, however, he had removed a portion of tissue and examined it microscopically, only to find that the disease was typically malignant.

Dr. Weir said that on several occasions he had found that cases of sarcoma had been temporarily benefited by mixed treatment. Long ago, in a case treated with the late Dr. Seguin, he had seen marked improvement in a tumor of the brain following the use of antisyphilitic treatment. Even cases of epithelioma would show this temporary improvement.

Dr. Van Arsdale said that some time ago a case had been presented to the New York Surgical Society, in which a similar condition had existed in the humerus. Most of those present looked upon the case as one of sarcoma, but the growth being cut down upon it was found to be an ossifying hæmatoma. In this case potassium iodide had been given for some time, but without good effect. The removal of the hæmatoma effected a permanent cure.

Dr. A. L. Fisk said that he had had three cases of sarcoma of the humerus, two being central and one subperiosteal. In these the *x*-rays showed a distinct change in the bone. It did not seem to him that from the *x*-ray photograph presented by Dr. Sayre any conclusions could be drawn, as the print was altogether too indistinct. A central sarcoma could be easily made out by an *x*-ray photograph, and could be differentiated from a central abscess. In the latter condition the shadow was decidedly brighter than in a case of central sarcoma.

Dr. Sayre explained that the lack of definition in his radiograph was due to the child having moved during the exposure. He thought also a longer exposure with a better vacuum would give a better radiograph.

Asepsis of the Hands; Gloves for Operations.—Dr. E. M. Foote, in some remarks on this subject, called attention to certain operating-gloves which he had found very useful. The ordinary methods of sterilization of the hands, he said, were successful only at the expense of much time and epidermis. Quite recently Mikulicz had recommended the use of silk gloves, which could be readily sterilized and changed during an operation as they became soiled. Of course, they were not impervious to moisture, but they could be made to shed water if thoroughly dried and soaked in a ten-per-cent. solution of paraffin in xylol before being sterilized. Such gloves were decidedly superior to rubber gloves, and much less clumsy to use. In order to avoid infection of the wound from the hands, the following points should be observed: (1) keep the hands as far as possible out of the wound: (2) wash and dry them, and cover with sterilized gloves; (3) for operations in the serous cavities and for difficult dissections, sterilize the hands by the well-known methods before covering them with the sterilized gloves.

The Gloves Should be Impervious.—Dr. George E. Brewer said that he had made a good many experiments with the ordinary methods of hand disinfection, taking cultures from the hands and nails, and had found that none of the methods of sterilization commonly employed were reliable. Experiments with formalin yielded somewhat better results than the other agents, but all were still unsatisfactory. Then, again, it should be remembered that, although the hands might be sterile at the beginning of an operation, it did not follow that they were so after a short time. The perspiration was in itself very poisonous. He therefore objected to the cotton gloves and to all gloves which were not impervious. He preferred the rubber gloves on this account, and his results since adopting these gloves in hospital practice had certainly been very much better than formerly.

Thorough Hand Disinfection Essential even with Gloves.—Dr. Weir said that it was true that hand disinfection had been the weak point in surgical technique. He had been using, though not continuously, lisle-thread gloves for a number of years. With them, as with the rubber gloves, the hands must be, in the first instance, thoroughly disinfected. If this part was neglected, and the rubber gloves were pricked or torn during an operation, the wound was liable to be infected. In this respect they were more dangerous, because the surgeon relied upon them implicitly, not knowing, in many instances, when they were torn.

The tendency was for the surgeon to be too lax in the first cleansing of the hands if rubber gloves were used. He thought if Dr. Brewer had contented himself only with bichloride of mercury and permanganate of potassium, he must certainly have had better results from the use of rubber gloves. But these methods of hand disinfection were not the best known; the use of alcohol or of nascent chlorine was far more efficacious.

Dr. Brewer explained that he had tried all except the last method of disinfection mentioned.

Dr. Coley said that in the last few months a series of bacteriological tests had been made at the Hospital for Ruptured and Crippled, and in a series of twenty-five or thirty cases the house surgeon had never failed to have his hands sterile.

Dr. Lilienthal said that he had used the cotton gloves without the paraffin, and liked them very well except for delicate manipulations in the peritoneal cavity. But the hands should be just as thoroughly disinfected as when gloves were not used. He heartily indorsed the principle that had been enunciated by Dr. Foote, *i.e.*, to keep the hands out of the wound as much as possible.

Trim the Finger Nails Close.—Dr. A. M. Phelps said that one very fertile source of infection was the introduction of the needle through the skin into the wound. He had seen Schede constantly operating under irrigation, and Schede had but little suppuration. He had also seen a good deal of suppuration in clinics in which gloves were used during the operations. It was important that the finger nails should be kept closely trimmed. If this point was attended to, if the hands were thoroughly disinfected, if care was taken not to infect the wound with the needles, and if the surgeon operated under irrigation with antiseptic fluids, there should be very little suppuration.

Prefers Rubber Gloves.—Dr. F. Kammerer said he had not found rubber gloves much more inconvenient than cotton ones; on the contrary, he had found that the thin rubber gloves possessed certain advantages. A cotton glove rarely fitted the hand well, and the top of the glove projecting beyond the finger-ends seriously interfered with the surgeon's manipulations. It did not seem to him that the perspiration was a great element of danger. The great advantage of the cotton gloves was the fact that the surgeon did not rub the tips of the fingers and the beds of the nails against the wound.

The Gloved Hand Must Bungle.—Dr. Robert T. Morris said that if one must use gloves in order to be up to date he preferred to be behind the times. The most skilful work must be done by the aid of a delicate and educated touch. If the hands were disinfected with nascent chlorine, there should be no occasion for the use of gloves. In peritoneal work he was sure the operation would be prolonged and bungled by wearing gloves.

A Compromise.—Dr. J. B. Walker said that the most important point seemed to be to give great attention to the scrubbing of the tips of the fingers and the beds of the nails. These parts were often neglected, while the back of the hand received a vigorous scrubbing. It might be well to have the assistants wear gloves, even though the operator avoided them for fear of obtunding his sense of touch.

Infection from Needle Punctures Avoidable.—Dr. Coley thought Dr. Phelps attributed far too much importance to the skin as a source of infection, for in the series of experiments conducted at the Hospital for Ruptured and Crippled the skin of the patient had been sterile in every instance. Moreover, in hernia cases, in which the sutures were passed through the skin, the skin was found to be sterile in ninety-five per cent. of the cases.

Have Few Assistants.—Dr. A. E. Gallant said that some surgeons had stated that their results had been better as soon as they had insisted upon their assistants wearing gloves. This should serve as a useful hint. It would be well to reduce as far as possible the number of assistants. It seemed to him that it was rare that more than two assistants would be required.

Dr. Kammerer remarked that occasionally he had been compelled to take off his gloves in order to get a better sense of touch, but this was very rarely needed.

Don't Sneeze while Operating.—Dr. Lilienthal said that theoretically we should go a little further and follow the advice of Mikulicz, to wear a covering over the head and across the mouth. Certainly it was conceivable that an inopportune sneeze might do a great deal of mischief.

Rubber Gloves Increase the Perspiration.—Dr. Van Arsdale said that he felt sure that he had seen a number of cases of laparotomy go wrong from perspiration falling into the wound from the forehead. Rubber gloves would be apt to make the hands perspire excessively.

Dr. Kammerer thought the surgeon was as well guarded from perspiration of the hands with cotton gloves as without them.

Delicacy of Touch Not Seriously Impaired.—Dr. Foote said that the point he had desired to make was that most surgeons did not sterilize their hands completely before beginning to operate. He had found that the delicacy of touch was nearly as great with the gloves that he had presented as with the bare hand. These gloves were very cheap, so that several pairs could be sterilized for an operation, and as the gloves became moist, from perspiration or otherwise, a clean, dry pair could be substituted. For ordinary operations it seemed to him just as unsurgical to put the fingers into the wound as it would be improper to eat meat at table without using a knife and fork.

Gastro-Enterostomy, Jaboulay-Braun Method, with Two Murphy Buttons.—Dr. Robert F. Weir read a paper on this subject, and presented an illustrative specimen (see page 541).

Dr. Kammerer said that his personal experience with the posterior method was limited to one case, as he had formerly practised the Wölfler method with various modifications. Although he had done the operation a number of times, he had lost a number of patients from the flow of bile into the stomach and the obstruction of the efferent loop of the attached duodenum. The recorded cases certainly seemed to prove that the Murphy button was borne very well in the stomach, and it was known that in the posterior operation suture was a very complicated procedure; hence the button should be always used in this operation. In one case, at least, he had seen violent symptoms arise from the button falling into the stomach and remaining there.

Dr. Lilienthal called attention to a Murphy button which he had devised for the purpose of preventing its slipping into the stomach. He had had one side of the button made larger than the other to obviate this difficulty, but had never subjected it to a trial test.

Dr. Van Arsdale referred to two cases in his own experience. In one he had used the Murphy button for a gastro-enterostomy done by the posterior method. The button fell into the stomach, and caused such persistent vomiting that the patient died of exhaustion thirteen days afterward. The autopsy showed nothing to account for this vomiting except the presence of the button in the stomach. In another case, at the Mount Sinai Hospital, he had used the suture, doing the posterior operation. He had not found that it had taken a much longer time, but he had used a very long incision in order to make sure that the opening would not close. The result in this case had been so satisfac-

tory that he had decided to employ this method in the future.

Exhibition of Brain from a Case of Apoplexy Subjected to Operation.—Dr. Robert T. Morris reported the case of a man, fifty-six years of age, who, on December 16th, while walking across the floor, felt that his right arm was becoming paralyzed. After five minutes his right leg was paralyzed, and at the end of thirty minutes he was unconscious and vomiting. Dr. Morris saw the case about forty-five minutes after these symptoms had developed, and had thought it might be well to open the skull with the object of allowing some of the blood to escape externally instead of into the brain, and so lessening the amount of injury which the escaping blood was likely to produce. The chosen point of attack was over the arm centre, because the arm was first involved. The idea was to follow the arm fibres until the clot was found. An opening was accordingly made with a trephine over the ascending parietal convolution. At this time the patient was so nearly moribund that the operation was for a moment discontinued. The meninges being opened, a very large quantity of pink serum escaped rapidly, spurting out under great pressure. The man's breathing immediately became regular, and his pulse dropped nearly to the normal and remained so. The serum was not distinctly bloody. The exploration was carried into the lateral ventricle, but very little serum was found there. He then went toward the island of Reil, and found some small clots escaping from the wound in the brain made by the instruments. The patient rallied as one would from a clot in the brain at this point. By the second day he was able to sit up and take some food. The effect of the operation was to relieve the general pressure over the left hemisphere of the brain. Although a clot was not found, enough serum was allowed to escape to prevent impending dissolution. The patient developed a hypostatic pneumonia on the tenth day, and died on the twelfth day.

Dr. Graeme M. Hammond said that he had had an opportunity of seeing this very interesting case within a few days after the operation. The man presented all kinds of aphasia—word deafness, word blindness, and inability to express a single idea. He knew the use of objects presented to him. He was hemiplegic on the right side of the body—arm, leg, and face. The autopsy was made a few hours after death. The first thing to attract attention was an enormous clot in the Sylvian fissure. The clot being scraped away, an opening was found in the fissure of Sylvius, leading inward. Most of the cerebro-spinal fluid had been drawn off during the operation. The hemispheres being opened and cut into just above the corpus callosum, a clot was found leading into the brain. There was present not only a large clot in the anterior region of the brain, but also an extensive clot extending longitudinally. Dr. Hammond said that the objection to operating early in a case of this kind was that it was often impossible at first exactly to locate the lesion. Thus the sensory aphasia in this case was apparently due to the compression of the Sylvian artery by the hemorrhage, and the consequent cutting off of the supply of blood to that part of the brain in which the centres affected were situated; indeed, this case was an excellent illustration of the difficulties and uncertainties of an early diagnosis. If the hemorrhage could be accurately located, the pressure could be relieved by such an operation, but it would not relieve the hemiplegia or any of the symptoms resulting from destruction of nerve tissue.

Dr. Weir said that he wished to commend Dr. Morris for his boldness in carrying out a correct surgical principle. In his own first operation for tumor of the brain, the tumor had not been correctly located; nevertheless he had made a huge opening in the skull and the patient had been immensely benefited. At this time (1879) he had advocated making a large opening in the skull, and subsequently he had advised operating in certain cases of cerebral hemorrhage, but he had been met with the objections just offered by Dr. Hammond. In 1894, in consultation with Dr. Dana, it had been decided to make an opening in such a case. An extensive exploration was made, but no clot could be found. At the autopsy, the next day, the condition was found to be one of embolism. In spite of this failure, he had felt convinced that it was justifiable to operate in cases which were steadily losing ground.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 9, 1898.

T. Mitchell Prudden, M.D., President.

An Anomaly of the Pulmonary Valve.—Dr. Warren Coleman presented, as an anatomical curiosity, a pulmonary artery showing four cusps instead of three. The fourth cusp was about one-third the size of the normal cusp, and was situated between the two posterior cusps. It was difficult to understand how the orifice could have been entirely closed by this anomalous valve.

Aneurism of the Basilar Artery.—Dr. Coleman also presented an aneurism of the basilar artery, which was interesting from a clinical standpoint. It had been taken from a man, fifty-four years of age. According to the history, when fifty years old he had suddenly gotten out of bed to go to the assistance of a member of his family who was ill, and had been almost immediately stricken with paralysis of the right side. He never regained the use of either the arm or the leg on that side, and contractures set in. He complained more or less constantly of headache and of pain in the right thigh. He death was preceded by coma, which gradually developed in the course of forty-eight hours. The autopsy revealed this aneurism, which measured 2 cm. in its transverse horizontal diameter, 1.5 cm. in the axis of the artery, and 1.5 cm. in the transverse vertical diameter. It was situated far forward in the artery, though apparently not involving either of the branches. On removing the brain from the skull it was found that the aneurism compressed the left crus cerebri, without affecting the spinal bulb. The symptoms, therefore, were those of interruption of the fibres in the left crus only. Death seemed to have been caused by occlusion of the aneurismal sac. The posterior communicating branches were exceedingly small, so that occlusion of this sac with a clot would deprive the spinal bulb of so much blood that death would result. The interior of the aneurism was filled with fresh clot.

Dr. Walter Lester Carr presented in connection with this case a specimen of aneurism of the basilar artery, which had been presented to the society in 1891. It had been taken from a man twenty-eight years of age. He had had a fall some years previously, and there was an indefinite history of syphilitic infection. The clinical symptoms were slow pulse, slow speech, and interference with respiration. There were pain in the cervical region and convulsions.

Dr. Eugene Hodenpyl remarked that he had a specimen very similar to the first one presented by Dr. Coleman, but in his case there had been a well-marked presystolic murmur during life.

Dr. W. P. Northrup thought that if the aneurism had developed slowly, like a tumor, a point would have been reached at which symptoms would have suddenly developed. He could recall at least two cases in which tumors of the brain, although growing

slowly, had suddenly given rise to symptoms. In one of these cases, without warning, the patient ceased breathing. The only lesion found at autopsy was a tumor at the convexity of the brain.

Dr. C. A. Herter said that on several occasions he had seen symptoms of an acute character develop in the course of a tumor, the ordinary symptoms of which had already developed, but he had never met with a case in which the first symptoms had been sudden in their development. It was quite a new idea to him, that an aneurism, without rupture or thrombosis, might give an acute hemiplegia as its first symptom.

Dr. Prudden asked if there was anything in the morphology of the blood-vessels which would justify the belief that the suddenness of onset of the symptoms had been the result of a sudden closure of neighboring vessels not directly connected with the aneurism.

Dr. Coleman replied that although a very careful examination had been made regarding this point, the result had been entirely negative. With reference to the point made by Dr. Hodenpyl regarding the existence of a murmur in the case having an anomalous pulmonary valve, he would say that his patient had been in Bellevue Hospital for a sufficient time to allow of an accurate clinical record being made, yet there had been no adventitious sound discovered about the heart.

Malignant Adenoma of the Stomach.—Dr. James Ewing presented a growth from the pyloric region of the stomach. It had been removed from a German butcher, twenty-seven years of age, who gave a distinctly alcoholic history, and who had been emaciating and becoming anæmic for just one year, though previously healthy. There were, during this year, no gastric symptoms. Shortly after admission to Roosevelt Hospital, on December 18th, he began to complain of pain in the epigastrium, worse after eating, and had occasional attacks of vomiting. On admission he looked excessively anæmic, and was very much emaciated. He complained chiefly of dyspnœa, general weakness, and pain in the epigastrium. The physical examination was negative. The urine was 1.005, acid, and was free from sugar, albumin, and casts. The excretion of urea was always low. The temperature during the two months he was in the hospital ranged between 97° and 100.5° F. Vomiting occurred nearly every day, and increased in quantity. It never contained either red or black blood, but was usually of a yellowish color. Hydrochloric acid was absent, and lactic acid was present in considerable quantity. The blood examination, on admission, showed red cells, 1,100,000; leucocytes, 6,000; hæmoglobin, 15 per cent. Under iron and arsenic the hæmoglobin temporarily increased, reaching 30 per cent. after one month. It then steadily declined, along with a diminution of red cells and an increase of leucocytes. On account of the absence of gastric symptoms the diagnosis was at first thought to be pernicious anæmia, although the morphology of the blood did not favor this opinion, as the chief character, besides the extreme reduction in the number and great variations in size of the red cells, was the uniform loss of hæmoglobin. No nucleated red cells were seen at any time. Toward the end there was a marked leucocytosis. After about six weeks a slight tumor was detected in the region of the pylorus, and at this time the vomitus resembled that from a dilated stomach. Masses of hæmatoidin, as well as shreds of the epithelial tumor, were discovered microscopically in the vomitus, which chemically had always shown absence of hydrochloric acid and presence of lactic acid. At the autopsy there were noted a small tuberculous cavity in the left pulmonary apex, adherent pericardium, marked fatty degeneration of heart muscle and liver, double ureter on right side, and a large ulcerating tumor of the pyloric region of the stomach, with firm posterior adhesions. The tumor involved the entire circumference of the pylorus, which was almost occluded, and extended irregularly over the pyloric end of the stomach for a distance of three or four inches. Its surface was very irregular, fungating in places, and deeply necrotic. The edges were moderately raised but not very dense. The stomach was greatly dilated, and contained two quarts of dark fluid of the microscopical and chemical characters noted in the vomitus. No metastases were discovered. The periportal lymph nodes were involved in the adhesions, but no others seemed to be affected. The microscopical diagnosis was malignant adenoma of the stomach.

Dr. Ewing said that the case was interesting: (1) because of the occurrence of this form of cancer in a patient so young; (2) because of the marked resemblance clinically to pernicious anæmia; and (3) because of the characteristic appearance of the vomitus toward the end of the disease. There were very few reported cases of malignant adenoma in patients of this age. The microscopical examination showed that the type of adenoma was much better preserved than usual.

Leukæmia.—Dr. Ewing also presented fresh specimens from a case of leukæmia. They were taken from a child of eleven years who was known to have had the disease at least four years. The blood was distinctly that of a myelogenous leukæmia, the largest percentage of white cells being myelocytes. The case had been under clinical observation for some years. In comparison with the weight of the child, the liver and spleen were excessiely enlarged. On section, the liver showed the portal canals infiltrated with new cells. The enlargement of the internal lymph nodes was a very prominent feature. The lungs showed small areas of fresh pneumonia and some areas of leukæmic infiltration. The heart was very considerably hypertrophied, and contained a characteristic leukæmic clot on the left side. The marrow of the sternum was extremely cellular, and of a much ligther color than normal.

Dr. Harlow Brooks said that three years ago there had been at Bellevue Hospital a case that had been diagnosed as pernicious anæmia after having been under observation for about three months. The clinical diagnosis had been verified by several blood examinations. At the autopsy he had found a typical malignant adenoma of the stomach situated in the region of the pylorus. Whether it simply happened to occur in connection with the anæmia, or whether the blood examination had been deceptive, he would not say, but he found it hard to believe the latter, as the examinations had been conducted by several well-known laboratory experts.

Dr. John H. Larkin said, regarding the right kidney from the case of adenoma of the stomach, that in addition to the double ureter he had discovered in the same kidney a small tumor which, upon microscopic examination, proved to be an adenoma of the kidney.

Dr. Ewing said that he had paid considerable attention to the character of the blood in this disease, and had yet to see a case of malignant disease of the stomach in which the blood was distinctly that of pernicious anæmia. It often resembled the blood of pernicious anæmia, though presenting distinctive characters of its own. These distinctive features were principally two, viz.: (1) The loss of hæmoglobin in the cells; and (2) the behavior of the leucocytes. In every case of ulcerating carcinoma of the stomach that he had seen, except the one just presented, there had been, from the first, distinct leucocytosis. As a

rule, the leucocytes were very much increased in carcinoma of the stomach, and were quite uniformly diminished in pernicious anæmia. Microscopical specimens were also exhibited.

An Experimental Study of the Toxic Properties of Indol.—Dr. C. A. Herter read a paper with this title, giving the results of his experiments on the lower animals and in man. He said that indol was produced in some quantity in the intestine, and was oxidized in the organism into indoxyl, which, in combination with sulphuric acid, formed the basis of the well-known indican or indoxyl reaction of the urine. Indol crystallized irregularly, had a melting-point of 52° C., volatilized readily, and possessed a characteristic fecal odor. It was produced by a considerable variety of bacteria, both pathogenic and non-pathogenic—*e.g.*, the colon bacillus, typhoid bacillus, the cholera bacillus, vibrios, etc. The indol used in these experiments was obtained from the putrefaction of large quantities of pig's fibrin. Indol underwent an important change within the organism, being first oxidized into indoxyl, and then changed into the sulphuric-acid salt of indoxyl. It was as indoxyl sulphate of potassium that the indoxyl formed within the organism left the body in the urine. When indol was injected in large quantity into the blood it soon disappeared and could not be recognized; yet the addition of a few drops of indol to a considerable quantity of blood outside of the body gave a different result, the indol being very readily recovered by distillation. This showed that the organism possessed the power of converting the indol very rapidly into some other body. It seemed probable that the main factor in the production of indol in the intestine was the presence of the colon bacillus. The common colon bacillus ordinarily produced indol when acting on proteid media. Indol in the intestine was transformed into indoxyl after absorption, and subsequently to indoxyl potassium sulphate. The indoxyl of the urine was convertible by oxidation into indican. The experiments detailed in the paper were directed to the investigation of: (1) Acute indol poisoning in rabbits and dogs; (2) chronic poisoning in rabbits; and (3) the effect of indol when taken into the stomach of human beings. It was found that intravenous injections of indol exerted marked toxic effects on the nervous system in dogs and rabbits, producing cardiac and respiratory depression, general prostration, marked contraction of the pupils, irregular clonic spasm, and increased reflex excitability, including increase in the activity of the knee-jerks. When fatal doses were injected the cause of death in every instance seemed to be cardiac, rather than respiratory, failure. Injections into the intestine caused more marked effects on the nervous system than intravenous injections. Small quantities of indol, when administered subcutaneously every day, caused profound disturbances of nutrition, and caused death in a few weeks. The immediate cause of death in chronic indol poisoning was not clear. The chief alterations were found in the liver, the capillaries of the lobules being much congested and the liver cells the seat of pigmentation. In marked contrast to the rabbits was the behavior of a monkey. A small monkey of about the same weight as the rabbits was scarcely affected by small doses of indol given for two weeks. In order to determine the effect on the human subject, three healthy men were given indol in increasing doses, beginning with 0.1 gm. in capsules immediately after meals. The first subject experienced slight frontal headache, and then colic, followed by diarrhœa. This was probably owing to the rather large doses of indol, as he received 0.5 gm. of indol. He was entirely well the next day. The doses of indol which were sufficient to cause symptoms in the first case had no effect on the second man, and it was only when large doses—1 gm. or more—were administered that symptoms were produced. These were, extreme insomnia and unnatural mental activity, and, toward the last, frontal and occipital headache. The third subject had frontal headache the greater part of the time, and some dizziness toward the end of the experiment. The knee jerks were increased. The symptoms wore away on discontinuing the indol. On a second trial, five days after the completion of the first, and under rather larger doses, the original symptoms returned. A third trial was made, extending over a period of eight days. In this experiment marked headache was noted only once, but there was an almost continuous sense of discomfort in the frontal region. The most prominent feature was the excessive lassitude. The urine gave no indol reaction before and after the experiment, but it was marked during the administration of the indol.

Dr. Herter then took up the consideration of the clinical significance of excessive indol production in the intestine, and its excessive absorption, as shown by a strong indoxyl reaction in the urine. He said that the first difficulty encountered was the absence of a satisfactory normal standard, as many persons had the indoxyl reaction constantly present in the urine. One should be cautious about concluding that the frontal headache was due to the indol absorption, although it was probably so produced in very exceptional instances. In the experimental cases the frontal headache was cleared up by out-door exercise. One might perhaps find in these experiments an explanation of the headaches and sensations of discomfort in the head observed in many persons suffering from constipation. The most important factors in determining individual susceptibility to indol were: (1) The character of the nervous system; and (2) the ability of the organism to transform indol into less toxic substances. It would seem from the observed effects of indol, taken in conjunction with the study of the clinical conditions in which the indoxyl reaction was markedly increased, that we were justified in believing that prolonged and excessive indol absorption was capable of causing frontal headache, abnormal cephalic sensations, and indisposition to mental and physical exercise. If prolonged, the latter might form the basis of a neurasthenic state. While we could not regard indol as an indifferent substance, we could not, on the other hand, regard it as a highly toxic one.

Dr. S. Bookman said that his experience seemed to show that indol was formed during pancreatic digestion and fermentation. He would like to know whether any gas analyses of the blood had been made to determine whether the oxidizing coefficient had undergone change in cases in which indol had been administered, and also whether the improvement observed from exercise might not be due to the absorption of oxygen and more active metabolism, with oxidation of the indol itself. It had occurred to him that it was possible that the potassium in the indoxyl potassium sulphate, when given in large doses, might be responsible for some of the prostration noted.

Dr. Ewing said that the paper gave much more definite information on this subject than he had been able to obtain elsewhere. Personally, he had experienced difficulty in applying the ordinary clinical test for indican, as it was very easy to add an excessive amount of the oxidizing agent. For this reason he desired further details regarding Dr. Herter's method of making this test. He also asked about the frequency and grade of indicanuria in albuminous putrefaction in other parts of the body than the intestine.

Dr. Bookman said that in applying the indican test he had found that a fifteen-volume solution of hydrogen peroxide and strong hydrochloric acid acted very uniformly and satisfactorily.

Dr. Herter said that he agreed with Dr. Bookman that it was not unlikely that the influence of exercise in clearing up the headache was dependent upon increased oxidation, but he did not think the potassium salts, under the circumstances, would be likely to exert any influence in rendering indoxyl more toxic than it had been previously. It should be noted that in his experiments the indol itself had been introduced, and not the potassium salts. He had made no gas analyses, and his reading of the literature had led him to believe that this method was likely to introduce many errors. Undoubtedly indol was produced under the influence of the pancreatic ferment on proteid material, but it might arise in the absence of the pancreatic juice, or even if the duct be tied. When large numbers of colon bacilli were introduced into the intestine below the point at which the pancreatic juice enters the gut, as he had done, there would be found to be a very rapid increase in the indoxyl in the urine. It was reasonable to attribute this, chiefly at any rate, to the action of the colon bacillus. As to the method of applying the indican test, he would say that he had met with the difficulty referred to by Dr. Ewing, and had found that this could be largely avoided by using a 0.5-per-cent. solution of ferric chloride in concentrated hydrochloric acid, mixing an equal volume of this and the urine, and then shaking out with chloroform. The putrefaction of proteids in other parts of the body was capable of giving rise to very strong indoxyl reaction in the urine. Cases in which abscesses had been opened had given a strong indoxyl reaction in the urine, and indol had been found in appreciable quantities in the abscesses themselves. As to the relationship between neurasthenic states and excessive absorption of indol, he would say that of thirty-two cases presenting the clinical characters of neurasthenia, twenty-one gave a strong indican reaction in the urine, and eleven a slight reaction or none at all.

The Report of a Case of Acromegaly, with Specimens, and of a Case of Hemorrhage into the Hypophysis Cerebri.—Dr. Pearce Bailey read this paper. He said that there were now on record over thirty microscopical examinations, with autopsies, but many lacked descriptive detail, and there were many notable discrepancies in the reports. It had been ascertained that the pituitary body is regularly diseased, usually in its anterior portion, that the thyroid is usually enlarged, sometimes atrophied, very rarely normal, and that the thymus is occasionally persistent or enlarged. The most constant visceral lesions were those of the pituitary and thyroid. The case reported was that of a woman, sixty-five years of age, who had been in good health up to five years before death. Then the hands and feet became enlarged and the seats of pain, extending up the limbs. There was no loss of muscular power at that time, and until her last illness she could walk and use the hands. The urine was albuminous, but there was no œdema of the extremities. Her death followed shortly after the sudden development of symptoms of uræmia and pulmonary congestion. The autopsy was made twenty-four hours after death. There was an extensive growth of hair on the face; the chin was prominent; the bridge of the nose was widened; the heart was moderately hypertrophied, but there was no valvular lesion; the muscular tissue was soft; there were acute congestion and œdema of the lungs, and the kidneys were the seat of chronic diffuse nephritis. The liver was normal. The cerebral dura was adherent to the skull and the pia mater was slightly thickened anteriorly. The brain weighed 1,284 gm., or about 72 gm. in excess of the usual weight. There was no gross deviation in the form of the convolutions. Examination of the ganglion cells by Nissl's method was negative. A mass of tissue occupying the position of the thymus was removed, but the microscope showed none of the thymus remaining. The thyroid weighed 84 gm., instead of 29.3 gm., the average normal weight. Its surface was firm and smooth, and on section a white, viscid fluid exuded. There was a number of small cysts. The gland substance proved, on microscopical examination, to be generally normal. The pituitary body was very much larger than normal, weighing 8 gm., instead of 0.6 gm. It was red and very soft, and the contents were whitish and semi-fluid. Sections showed three distinct portions, united by a common capsule. These portions were: (1) The smallest, or posterior lobe, which was somewhat more cellular than normal; (2) the middle portion or glandular lobe, the chief characteristic of which was its vascularity; and (3) the anterior portion, composed of fibres and cells, with deeply staining nuclei. In other words, there were a pituitary body and an outgrowth from its anterior lobe. The tumor might be regarded as an adenoma.

The second case reported was that of a male, fifty years of age, who was admitted on February 13, 1897, to St. Luke's Hospital, to the service of Dr. Van Horne Norrie. The patient was comatose on admission, and died within twenty-four hours. He had been moderately alcoholic, and for several years previously had had paræsthesiæ of the lower extremities and back. Shortly before admission he had complained of impairment of vision and pain under the eyes, and later there were nausea, vomiting, and blindness. He lay on the left side almost continuously; the pupils were moderately dilated; there were paralysis of the internal rectus and ptosis on the right side. There was no other paralysis and no optic neuritis. At the autopsy, there was no external evidence of acromegaly. On examining the brain, a high degree of endarteritis of the basilar artery was noted. Occupying the sella turcica and projecting about 3 mm. above it, was a mass which, on microscopical examination, proved to be the encapsulated pituitary body enlarged to three or four times its normal size. An extensive hemorrhage had taken place into it. There was an endarteritis of many of the small vessels in this mass. The parenchymatous hypertrophy of the pituitary body must have antedated the hemorrhage. The latter was the result of rupture of some of the diseased vessels in the pituitary body. The speaker said that it was possible that this case represented an early stage of acromegaly.

The society then went into executive session.

Bone Setting in Rural England.—A writer in a contemporary English weekly records the following amusing account of how bone setting is practised in the country districts of parts of England: "An old woman I once knew had a kind of shibboleth which she repeated in all cases of injury of the elbow. 'There are two small bones at the elbow,' was her remark. Now, there are not two small bones at the elbow, as every ambulance student knows. Still the old lady held on her way rejoicing. I have even heard it seriously asserted that this old lady had 'mended a man's broken neck' when the surgeons had given him up as a hopeless case. A capital story of bone setting is that of the Scotch laddie, Jock by name, who, after being carried by his mother an unwilling patient to the bone man to get his leg set, was asked if the manipulation had hurt him. 'No,' said Jock; 'it dinna hurt me.' 'I told you it wadna be painful,' said his mother. 'Ah,' replied Jock, 'nae wonder! Ye see, mither, I just let him fumble wi' tha sound leg.'"

Correspondence.

HEMORRHAGE IN CATHETERIZATION OF THE URETERS.

To the Editor of the Medical Record.

Sir: In the article of Dr. Vineberg, in the Medical Record of February 5, 1898, I find the words: "Casper states that it [bleeding] occurs in fifty per cent. of his cases." This is a mistake; I have spoken only of a few blood corpuscles which are found in fifty per cent., after the urine has been centrifugalized, but have not said that macroscopical bleeding occurs thus often. And, moreover, that was in the beginning of the employment of the method; now, after I have had more experience in catheterizing the ureters, I find even less (no more than in ten per cent. of the cases) microscopical bleeding.

Will you kindly publish this correction, which, I think, is in the interest of the science?

Leopold Casper.

Berlin, March 20, 1898.

TREATMENT OF HYDROPHOBIA BY THE HEALTH BOARD.

To the Editor of the Medical Record.

Sir: In your issue of March 26th, in the column under the heading "News of the Week," there is a paragraph entitled "The Paternal Government of Our Health Board." If you will permit me space in your valuable columns for a few words, I will give a brief description of this new department. I am in a position to do this, being one of the physicians in charge of the new work referred to.

For about a year now I have been experimenting with and investigating, in conjunction with Dr. R. J. Wilson, the Pasteur method of immunizing persons against hydrophobia. The treatment, which requires a large amount of apparatus, a laboratory, animal house, etc., certainly cannot be employed, as at present used, by physicians generally; and as there is no place in the city where the poor can be treated free, why should not the city provide for them?

The mortality from bites by dogs proved mad is fully ten per cent. for all parts of the body; much higher for exposed regions. According to Pasteur and other investigators in this field, it has been reduced to less than one per cent. by the dried-cord treatment.

The board of health opened this new department three weeks ago, for the benefit of the public. Since this time eleven people have applied for treatment, nearly all from Richmond Borough, where there has been a serious outbreak of hydrophobia in dogs.

The patients applied for treatment as follows: Two from West New Brighton on the 26th, after having been bitten. One of these patients was bitten twenty-eight times on the hands and arms, and badly lacerated; the bites were not cauterized. The other patient was bitten nine times in the arm through the sleeve. In the first case the prognosis given was very grave, owing to the lapse of time before treatment was taken and the nature and seat of the bites. The patient bitten nine times in the arm was not in so serious a condition, but still the prognosis given was grave. The dog which bit these people had previously been sent to the laboratory for examination. After autopsy, inoculations were made from the medulla into rabbits and guinea-pigs, all of which died of typical rabies; also a second series of animals inoculated from these rabbits and guinea-pigs, proving beyond a question the diagnosis of hydrophobia.

Besides these people mentioned above, another person bitten by the same dog applied for treatment before it had been opened to the public.

Several other dogs, supposed to have been bitten by this same dog, have died presumably mad; one of them infected two persons with saliva. They first went to the Pasteur Institute for treatment, then came to the health department. They were advised to continue where they began. One of the dogs bitten by this rabid dog, and which subsequently died under suspicious circumstances, was sent to the laboratory, and after autopsy inoculations were made in rabbits and guinea-pigs, which are now under observation.

Another dog in West New Brighton, apparently with no connection between it and the first cases, became rabid and died in three days. The diagnosis of rabies was made by an able veterinarian. Its body was sent to the laboratory, inoculations were made in rabbits and guinea-pigs, and the animals are now under observation. This dog bit two people, who are now undergoing treatment by the health department.

Besides these cases, two people who applied for treatment were advised not to take it, as the dogs which bit them were manifestly not mad. Two other people have just applied for treatment, who were bitten by a dog supposed to have been mad. The dog was killed, and is to be sent to the laboratory for investigation.

The above facts give the amount of work done so far, but the cases will be reported much more fully later, with results of treatment, etc. I think these facts will prove that there is room for this new department, and that the field of the physician will not be encroached upon. Follen Cabot, M.D.

128 East Thirty-eighth Street.

A REPLY TO DR. VINEBERG—ABDOMINAL HYSTERECTOMY—ACUTE PUERPERAL SEPSIS.

To the Editor of the Medical Record.

Sir: Dr. Vineberg writes a reply to my remarks in a discussion concerning the specimen of a uterus which he presented at the meeting of the obstetrical section of the Academy of Medicine on February 24th. It is to be regretted that the doctor makes this a personal matter, there being no justification for such a course, or for adopting this mode instead of making his final reply at the time of the meeting, my remarks having been made only in the interest of science, and not adversely to the gentleman, but only to his procedure. This compels me to answer him through your columns. Although the doctor states that his reply must not be taken as an implied criticism, I do not see how it can be construed otherwise, he selecting only my name in his reply. The doctor, however, has said nothing in his answer which in my opinion makes his procedure valid, and I still adhere to the views expressed in the discussion, printed in the number of your journal for March 12th—namely, that I have not seen a case of "acute puerperal sepsis" cured by such operation. In the cases of acute puerperal sepsis to which I allude, I do not include those having accumulations of pus somewhere in the pelvis, or cases of puerperal sepsis due to remnants of placenta or decidua remaining in the uterus. I have operated upon a goodly number of women ill with acute puerperal septic peritonitis, hoping to save one or another, but so far in vain. The condition found is a large flabby uterus, the Fallopian tubes congested but not containing pus, the ovaries macroscopically normal, the intestines distended and the peritoneal surface more or less congested, no adhesions at any place—in short, a septic peritonitis. The patients give the

history of having been delivered from two to six days previously, when the trouble began with a more or less marked chill; but I have seen a number of cases in which the chill was absent, and the only complaint, so far as the patient was concerned, would be a feeling of heat and weakness. The temperature varies from 103° to 106° F; the pulse ranges from 130 to 160 and is feeble and easily compressible; the abdomen is distended; the face has the characteristic appearance—sallow, with slightly flushed cheeks and pinched alæ nasi. Death takes place in such cases in from the fifth to the tenth day after the delivery.

If a major operation is performed, such patients die earlier, usually within thirty-six hours after the operation, the shock of the surgical procedure contributing to this. Such has not been alone my experience, but also the experience of all those personally known to me.

On the other hand, all of us who have had sufficient experience can recall cases of the type to which Dr. Vineberg's belong, presenting symptoms as aggravated and even more so than his cases, which ended in recovery without an abdominal hysterectomy. The views which I expressed in the discussion alluded to were shared by all who spoke at that time; and, in fact, by every one who saw the two uteri presented, one of which contained a good-sized piece of adherent placenta, which might have been removed, thereby removing the focus of infection and avoiding the abdominal hysterectomy which the doctor did.

H. J. Boldt, M.D.

54 West Fifty-First Street, New York.

New Instruments.

SEVERAL NEW GENITO-URINARY INSTRUMENTS.[1]

By Ferd. C. Valentine, M.D.,

New York,

Professor of Genito-Urinary Diseases, New York School of Clinical Medicine; Genito-Urinary Surgeon, West Side German Dispensary; Genito-Urinary Consultant, United Hebrew Charities, etc.

A New Urethral and Intravesical Irrigator.—The favor into which copious urethral and intravesical irrigations for the treatment of gonorrhœa and its sequelæ have risen in all parts of the world has called for a simpler means of accomplishing the desired end. I thought I had attained this when I published my last article on the subject.[2] But the apparatus then advocated had defects which are overcome in the one I have the honor of showing now. Aside from more sightly appearance, it has the marked advantages of greater simplicity, less liability of breakage, and far greater facility of operation. Indeed, so simple is it that the complex directions required for its predecessors become entirely unnecessary now.

It consists of an elevator, which, however, is a convenience only for those who have many irrigations to perform daily. The movable collar can be substituted by one fixed at nine feet from the floor. The percolator in which the liquid used is placed can be set into the ring so fixed or, if the elevator is used, hoisted by a cord and made fast to a plain hook.

The essential part of this irrigating apparatus is its new stopcock and shield. The latter is of metal, varnished to withstand the effects of potassium permanganate, which is most frequently used in these irrigations. The shape of this shield is that segment of a globe which experience has shown to be all-sufficient for the reception of the fluid as it spurts from the meatus and for guiding it into the basin held by the patient. The advantages of metal over glass, in a shield, are too evident to merit much discussion. Theoretically, glass conveys the idea that the surgeon can visibly guide his work through its transparency. As, however, at the very beginning of irrigation the glass becomes blurred from the escaping fluid, the employment of this material as a shield becomes illusory. Moreover, the metal shield, being about one-fourth of a globe, leaves the meatus and glans in plain view, while it is large enough to serve all the purposes for which I originally devised this portion of the apparatus. The new shield has a little ring by which it may be suspended from a cup hook when not in use, thus preventing doubling and consequent premature breaking of the rubber tube.

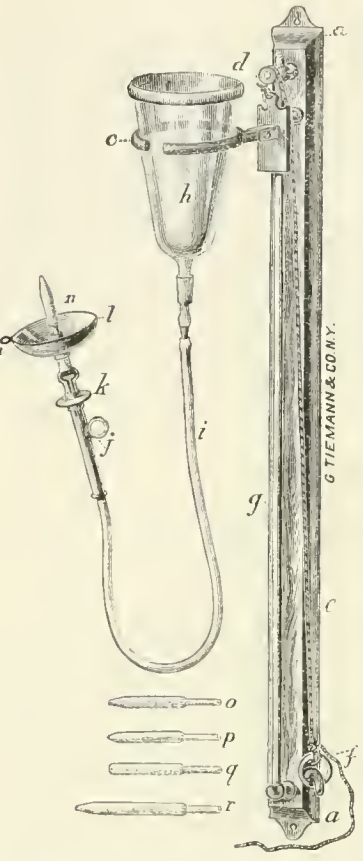

Fig. 1.—Valentine's Urethral and Intravesical Irrigator. *a*, *a*, Board with metal ends, the upper part thereof to be attached to the wall, nine feet from the floor; *c*, sliding ring to hold percolator; *d*, pulley for readily lowering the percolator to fill it; *e*, cord by which percolator is raised and lowered; *f*, ring slipped over hook to hold percolator in place when filled for use (experience has shown that this elevation suffices to overcome the most resistent compressor; minor pressure is easily regulated exactly as required by the stopcock); *g*, brass rod, on which percolator collar slides; *h*, glass percolator; *i*, soft-rubber tube, six and one-half feet in length; *j*, ring of stopcock (in irrigation, the fourth finger of the right hand is passed through this ring; *k*, flange, moved forward and backward by right thumb to vary the flow from merely sufficient to wash the prepuce, glans, meatus, etc., to a full stream, sufficient to enter the bladder, which a little experience enables the operator to do painlessly); *l*, metal shield to catch irrigating fluid as it spurts from the meatus, and direct it into the basin held by the patient (in male as well as female patients, irrigation can thereby be accomplished without soiling the body or clothing); *m*, ring to suspend stopcock when not in use; *n*, stopcock attached to tube; *o*, pointed glass nozzle for average meatus; *p*, dome-shaped glass nozzle for a very large meatus; *q*, flat glass nozzle for a very small meatus; *r*, long nozzle for female urethra.

The shield is a part of the new stopcock. This latter consists of a simple metal tube with two of its sides cut, into which heavily tipped strips of the same metal are sunk. They are managed by a ring, which is easily moved forward or backward. These motions practically cover the whole technique of urethral and intravesical irrigations. When the ring is as far forward as it can be pushed, the rubber tube within is closed. Slightly drawn back, it allows enough fluid to escape to wash the prepuce, glans, and meatus; if it is farther drawn back the jet becomes as strong as may be desired for urethral irrigation. When the ring is entirely drawn from the cut portion of the tube it yields a pressure sufficient to overcome the strongest compressor, and this makes intravesical irrigation easier than was possible with the instruments formerly recommended. The position of the patient, the indications for treatment, the solutions employed, and all other details were fully described in the Medical Record for June 5, 1897.

[1] Demonstrated before the genito-urinary section of the New York Academy of Medicine, December 14, 1897.

[2] Valentine: "Further Improvements in Urethral and Intravesical Irrigations," Medical Record, June 5, 1897.

Albarrán's cystoscope marks an era in examinations of the bladder, ureters, and kidneys, and in the treatment of these organs. Its optical portion is similar to that of Nitze's cystoscope. The lamp, however, gives a greater illuminating intensity, heats far more slowly, and can more easily be changed. Its shaft is much thinner than that of any other cystoscope, but the prism and lenses are so arranged as to expose a much larger surface of the interior of the bladder.

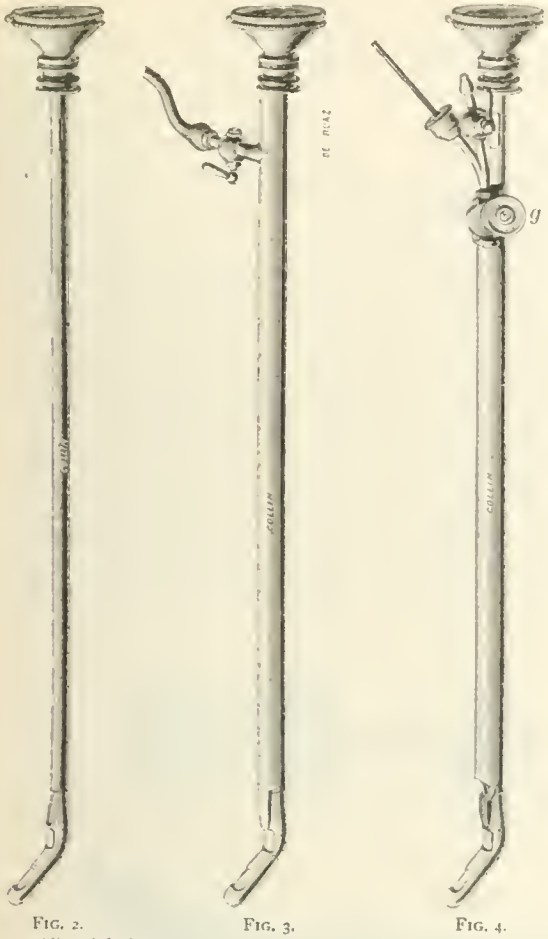

Fig. 2. Fig. 3. Fig. 4.

Fig. 2. Albarrán's Cystoscope.
Fig. 3. Albarrán's Cystoscope with Irrigating Attachment in Place.
Fig. 4.—Albarrán's Cystoscope with Attachment for Ureteral Catheterization.

The attachment for ureteral catheterization is easily made a part of this cystoscope. Complicated as it appears in illustration, its mechanism is exceedingly simple. Its essential feature is the movable guard, which can give the ureteral catheter any curve that may be required, while the instrument is in the bladder. This is accomplished by means of the eccentric wheel *g*. I do not recall having seen anywhere in the writings of Nitze, Casper, Brenner, or others, that lateral directions can be given the ureteral catheter by twirling its distal end. This as I have often shown is easily done, and ureteral catheterization accomplished without turning the cystoscope, whereby view of the mouth of the ureter is readily lost. But an inexpressibly great impulse is given ureteral catheterization by Albarrán's guard, which curves the catheter from behind forward, between the vertical and horizontal positions, without tilting the instrument. The percentage of successful ureteral catheterizations is vastly increased by this simple appliance.

Behind the wheel which moves the intravesical guard a nipple with stopcock is attached. This leads through a tube to the prism and lamp, which can be cleansed of blood, pus, or mucus, by a slight injection of boric-acid solution, while the cystoscope is in the bladder. This improvement does away with one of the elements which frustrated even simple cystoscopy in many instances. The same part of the apparatus also enables the surgeon to draw off an excess of fluid from the bladder, to increase its contents if they are not sufficient, or to substitute clear fluid when the fluid in the bladder has become turbid.

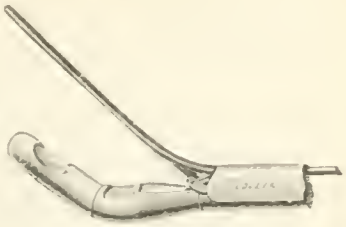

Fig. 5.—Tip of Albarrán's Cystoscope, showing one of the angles to which the ureteral catheter can be bent within the bladder.

The irrigating attachment is naturally simpler still than the one before outlined. Its large canal renders washing the bladder easy during cystoscopy.

Albarrán sums up his description[1] as follows:

"1. The same instrument can be used as a simple cystoscope, an irrigating cystoscope, or as a ureteral cystoscope. This instrumental combination is of a degree of importance from an economical point of view, owing to the high price of cystoscopes. As regards ureteral catheterization, I would call attention to the following advantages:

"2. The visual field of the instrument is very large, which permits finding the ureters as easily as with the best cystoscopes ordinarily used.

"3. The luminous intensity of the lamp gives a strongly lighted field, which greatly facilitates all manœuvres.

"4. The ease with which ureteral catheterization can be performed in the male and the female is truly remarkable. The precision of movement given the extremity of the sound is such that I have often performed catheterization in less than half a minute, and several of our pupils in the Hôpital Necker have readily learned this catheterization. This instrument has made ureteral catheterization common, almost daily, in the service of my master, M. Guyon.

"5. The changes which can be given the ureteral sound are so extended that I always, up to the present, have succeeded in catheterizing all cases, even those in which the prostate was hypertrophied.

"6. The sound penetrates the ureter in the most appropriate direction, *i.e.*, from below upward and from within outward.

"7. The instrument is perfectly watertight.

"8. The ureteral attachment which carries the sound is separable from the optical portion. It can be placed in the oven; thus the only part which might leave something to be desired regarding cleansing can be positively sterilized."

The author's further claims for his ingenious instrument have been mentioned before.

The catheters, which can be made to penetrate the ureter, even the pelvis of the kidney, are modifications of ordinary urethral catheters. Up to 12 F. can be introduced over the Albarrán guide sound if the calibre of the ureter permits. They can be left *in situ* as long as required, and can be changed whenever necessary, merely by reintroducing the guide sound through their lumen and stripping the catheter from it. The advantage of being able continually to drain a kidney, as for instance in a fistula after nephrotomy, is self-evident. To do this without repeated cystoscopy is of incalculable benefit to the patient.

Further description of this instrument, however, would lead to an extended paper on ureteral catheterization, which would be far beyond the scope of the present demonstration.

[1] Albarrán: "Technique du Catheterisme Cystoscopique des Uretères." Revue de Gynecologie et de Chirurgie Abdominale, No. 2, May–June, 1897.

Kollmann's irrigating dilators are certainly most ingenious combinations, by which urethral dilatation and irrigation can be performed at the same time. Both instruments, (*a*) for the anterior urethra and (*b*) for the posterior urethra, have channelled blades, through which the fluid used for irrigation (preferably hot two-per-cent. boric-acid solution) can be passed while dilatation is being performed. The liquid so injected escapes from the distal end of the dilator into the urethra; the shield in front, being closely pressed upon the glans, prevents its flowing from the meatus. It consequently finds its way through an orifice near the proximal end of the instrument, which connects with the lower stopcock, to which a rubber tube is attached to conduct the fluid to a receptacle conveniently placed.

While these instruments have acted satisfactorily in my hands thus far, my experience with them in the past two months I have used them is naturally too limited to warrant reporting any advantage over post-operative use of the new irrigator before outlined. Theoretically, however, there should be at least convenience in this immediate connection of dilatation with irrigation, especially in cases of obdurate chronic urethritis.

These irrigating dilators, as they are used without rubber covers, cannot be recommended to practitioners, unless they, like my present audience, have by large experience in urethral instrumentation acquired that special delicacy of touch which will prevent injury to the organ.

Fig. 6.—Kollmann's Irrigating Dilator for the Anterior Urethra.

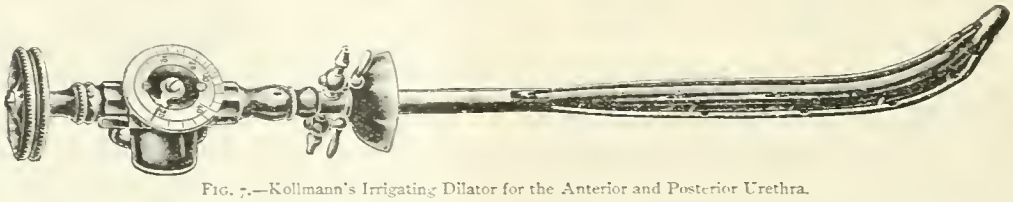

Fig. 7.—Kollmann's Irrigating Dilator for the Anterior and Posterior Urethra.

Wossidlo's centrifuge, like the new urethral and intravesical irrigator, is an apparatus which will prove as useful to the general practitioner as to the specialist. It consists essentially of a heavy base, on which the revolving plate is carefully balanced. It differs from the ordinary top centrifuge essentially in that it requires no clamping, but can be placed anywhere, even on the microscope table, where it makes no noise and causes no vibration. After use it can be put out of the way of other work, certainly a most desirable feature when office space is limited. While Wossidlo's centrifuge will do all the work required of such an apparatus, its price is lower than that of any other thus far placed on the market.

My new urethral and intravesical irrigator is manufactured by Collin (Paris), Heynemann (Leipzig), and Tiemann (New York). Albarrán's cystoscope is made by Collin; Kollmann's irrigating dilators and Wossidlo's centrifuge are made by Heynemann.

London Pauperism.—A census of London paupers, taken on the last day of the first week of March in the years named, shows that the number of paupers was, in 1898, 105,882; in 1897, 105,694; in 1895, 137,298. —*London Times.*

AN IMPROVED HAGEDORN NEEDLE.

By H. F. BIGGAR, Jr., M.D.,

Cleveland, Ohio.

There have been many devices brought forward in the direction of new needle forceps for needles of the Hagedorn type. These have been as intricate and complicated in many instances as they were varied in construction. Few have given entire satisfaction.

The best forceps have always been the simplest in construction, that could be adapted to any cavity or position.

My aim has been not to adapt the holder to the needle but to change the needle to fit the simplest form of forceps. The accompanying cut represents an improvement on the popular Hagedorn needle, so that it may be firmly and securely held by any style of needle forceps.

The cutting-edge and point and about one-half the length of the shaft consists of an ordinary Hagedorn. Then the plane of the shaft changes at 90°, and the remainder of the needle, the part grasped by the forceps, lies horizontal to the vertical point.

The needle is made in six sizes and curves by George Tiemann & Co., who have made them for me for over a year. In corresponding with Messrs Tiemann & Co., I learn that Dr. J. A. Dibrell, of Little Rock, Ark., has previously devised a similar needle, of which I was ignorant. But in surgical work I find the needle so convenient and of such service as to warrant bringing it before the profession.

Chest Disease in London.—The Royal Hospital for Diseases of the Chest in London has just published its annual report, and it is stated therein that the total number of in-patients under treatment during the year was 740, of whom 577 were discharged relieved or convalescent, 94 died, and 64 remained in the wards at the end of the year.—*London Times.*

Growth of Town Population in Japan.—The last Japanese census shows that in Japan, as in many other countries, the population tends more and more toward the towns. In 1886 not quite two per cent. of the total population lived in towns of over 10,000 inhabitants, while in 1894 the proportion was over sixteen per cent., although in the mean time the total population had increased from 38,500,000 to nearly 42,000,000. In 1886 the number of towns with more than 10,000 inhabitants was 117, in 1890 it was 188, and in 1894 it was 205. Four and one-half millions of people lived in these towns in 1886, and 6,750,000 in 1894.—*London Times.*

FORCEPS AND CURETTE FOR THE REMOVAL OF ADENOIDS.[1]

By WALTER F. CHAPPELL, M.D.,

CONSULTING LARYNGOLOGIST TO THE LOOMIS SANITARIUM; SURGEON TO THE MANHATTAN EYE, EAR, AND THROAT HOSPITAL, NEW YORK.

The best means of removing adenoid tissue from the nasopharyngeal space has been a fruitful source of discussion ever since its importance was fully recognized. The location and formation of this space render it somewhat inaccessible for operative procedures, excepting through the mouth. Some well-known specialists have recommended the nasal passages as the best route to the nasopharynx, but it must be some very unusual condition which would make such a selection preferable. Various instruments have been devised for the removal of adenoid tissue, and many claims of success and superiority have been made by their various advocates. The forceps and curette are, however, generally conceded to give the most satisfaction, and are the instruments which will be considered in this brief paper. I present samples of some of the forceps and curettes to be found in the instrument shops of the city. Of course, all the gentlemen present are in a general way familiar with them, and each has his favorite instrument, but this presentation is only to refresh our memories for discussion. The statement is often made that the removal of adenoids is a simple operation and safe for any physician to perform. To be sure, free hemorrhage is easily obtained, and neither the patient nor the doctor can always tell just what has taken place; and it is not until later, when otitis media, unilateral deafness, dry pharyngitis, or some other complication is encountered, that the importance of some experience in these matters is realized. How often members present this evening have had children brought to them, who have been operated upon without any relief! One of the causes of incomplete removal of adenoid tissue, unnecessary destruction of mucous membrane, or other damage in the nasopharynx, is the forceps or curette employed being too large. From measurements I have made after death on infants under three years of age, I am convinced that both the forceps and curette, especially the latter, on sale are far too large for safe and satisfactory use. This is of special interest when we consider the large number of young children who suffer from adenoid growths. In an examination of two thousand children which I made about nine years ago, the greatest number occurred in children under six years of age.

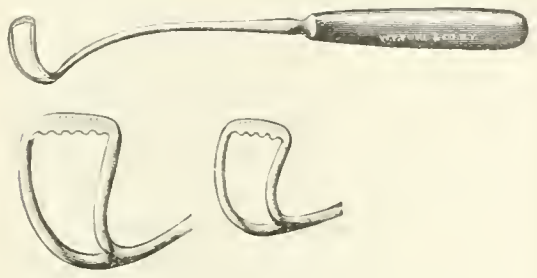
A recent examination of the records of the Manhattan Eye, Ear, and Throat Hospital shows that for the five years preceding 1898 four hundred and thirty-seven infants under three years of age were brought to the hospital for treatment of the throat. One hundred and sixty-seven of these had adenoid tissue in the nasopharynx, the greatest number ranging from two to three years of age. There were quite a number under one year, and four in whom the growths were congenital. In infants under six months I have always found the index finger too large for a satisfactory digital examination. Until I employed a curette made on the measurements referred to, I was not satisfied with the treatment of the nasopharynx which I had been able to employ in young infants. In my experience, to obtain the best results with a minimum amount of danger, we should use instruments of sizes based on actual measurements of the nasopharynx at various ages.

Whether we shall use the forceps or curette, or both, is another matter for discussion. For some time the forceps had the preference, but at present the curette has considerable favor in this country. Many use both instruments, selecting that which seems most suitable for the case in hand. Regarding the forceps, one of the favorite arguments in their behalf is that large masses of tissue can be removed and reserved to show how much has been taken away. This can be done equally as well with the curette in skilled hands, especially if the child is in the erect posture. Forceps opening laterally or antero-posteriorly in a space so small as the nasopharynx involve considerable danger to the surrounding parts. They remove growths by piecemeal and are apt to leave small tags behind. To be safe and to obviate all these difficulties in using the forceps, we are told to pass the finger into the nasopharynx and guide the blades of the forceps to each growth. This unnecessarily prolongs the operation, making from six to twelve insertions of the instrument necessary in every case. Furthermore, in my experience it is not an easy matter to employ the forceps with your finger in the nasopharynx of a child. The movement of the curette, on the other hand, is an antero-posterior one of a sweeping character, extending from the posterior margin of the septum to the free margin of the soft palate in the median line. This takes in the whole surface of the nasopharynx on which adenoid tissue is usually found, and needs only the guidance of an experienced hand. Two or three skilful applications should clear the nasopharynx in ordinary cases. The rapidity and exactness with which this can be done justifies, in my opinion, our dispensing with an anæsthetic in many cases. The advantage of this is very obvious. In the writer's opinion it is also impossible to acquire the same delicate touch with the scissor-like movement of the forceps that can be acquired with the curette, which should be the same as a pen in the hands of a skilled penman. In the selection of a curette, one should be chosen of suitable size for the age, and, if possible, of the shape of the nasopharynx. The blade should be narrow, so that it will engage near the septum, and should not look directly backward, or it will strip up tissue unnecessarily, especially on the posterior wall of the pharynx. The width of the fenestra at the point of junction of the arms with the shaft of the curette should be one-half of its width at the blade. This is important, as, if narrower, it allows the instrument to slip over the growths without thoroughly engaging them; if wider, it is grasped by the soft palate and interferes with the rapid use of the instrument on the posterior wall. The shank of the curette may be straight or curved, preferably the latter. Raising the handle then throws the blade forward, and, in place of the blade embedding itself in the mucous membrane of the posterior wall, it almost picks the growths from the mucous membrane.

Before beginning the operation, locate as clearly as possible the amount and situation of the adenoid tissue. Then pass the instrument behind the soft palate, depressing the handle until the blade touches the septum and roof of the vault. A fair amount of pressure should then be exerted, so as fully to engage the tissue behind the septum, before the backward movement is begun. The latter is made quickly and with very moderate firmness, until the posterior wall is reached, when the pressure is lessened by elevation of the handle of the instrument. I wish to protest against the great amount of force employed by some operators. A well-known specialist has frequently remarked in my presence that he went to the bone every time, and I have been present when the periosteum was certainly denuded. To my mind there is no excuse for this, and the amount of pressure used is one of the points we should all carefully determine, and endeavor to accomplish this operation by skill and not by force.

[1] Read before the section on laryngology of the New York Academy of Medicine, February 23, 1898.

The curettes here shown have been used by me for several months at the Manhattan Eye, Ear, and Throat Hospital. They have been changed from time to time as experience suggested, and in my opinion cover fully the requirements for this operation. The width of the smaller curette and length of its fenestra are based on the measurements I have referred to, and it is intended for use in infants and children up to their fourth year. The larger curette is based on similar measurements in children from four to fourteen years of age, but may also be used for adults. The cutting edge of the blade



may be straight or coarsely serrated and not very sharp. At first sight the serrated blade might suggest teeth which would tear the mucous membrane, but it does not if it has the right pitch, and really preserves the mucous membrane, as it crushes and rakes off the growth with very light pressure, leaving the membrane intact. The smallest points of adenoid tissue are readily caught in this form of knife, and can be preserved for examination if desirable.

The points in favor of a curette may be summed up as follows: It shortens the time required for the operation; frequently anæsthesia may be omitted; it minimizes the danger of injury to the Eustachian tube, septum, or soft palate, and of any unnecessary sacrifice of mucous membrane.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending April 9, 1898:

	Cases.	Deaths.
Tuberculosis	146	132
Typhoid fever	8	3
Scarlet fever	128	11
Measles	329	9
Diphtheria	145	15
Laryngeal diphtheria (croup)	13	4
Chicken-pox	26	0
Cerebro-spinal meningitis	0	4
Pertussis	1	0
Erysipelas	1	0
Parotiditis	2	0
Small-pox	1	0

Accountability of the Physician.—The law does not require of a physician or surgeon absolute accuracy, either in his practice or his judgment. The law does not hold physicians and surgeons to the standard of infallibility, nor does it require of them the utmost degree of care or skill of which the human mind is capable, but that, while in the practice of their vocation, they shall exercise that degree of knowledge and skill ordinarily possessed by members of their profession. This is the declaration made by the supreme court of Nebraska, in the case of Van Skike *vs.* Potter, December, 1897, which was an action brought to recover damages from Drs. Potter and Reynolds for alleged negligent treatment of a kneecap fracture. The trial resulted in a verdict and judgment in favor of the doctors, which the supreme court affirms. The evidence, the supreme court holds, sustained the finding of the jury that the defendants did not contract with the plaintiff to effect for him a permanent cure, and did not contract to visit and treat him until he was cured. As to whether they had pursued the proper method in setting his kneecap, by wiring the fractured portions together, the supreme court says: "As is usual, the experts for the plaintiff agreed with his contention, and the experts on behalf of the defendants agreed with their contention": and it decides that they were not guilty of negligence in the treatment given the plaintiff, including the leaving the point of a drill in the bone, when broken off in drilling a hole in one of the pieces of the kneecap, owing to a movement of the plaintiff's leg. Upon the issue made by the pleadings as to whether the defendants agreed to visit and treat the plaintiff until he recovered, the court holds that they were properly permitted to testify that at the date of their last visit to him they informed him that they should not return unless they should be requested so to do. It also holds that in such a case text-books on surgery, though standard authority on the subject, could not be read to the jury as independent evidence of the opinions and theories therein expressed or advocated. —*Journal of the American Medical Association*, March 12th.

The Effect of Water Pressure.—It is a remarkable fact, says an English paper, that the very means of life may be the cause of death. A whale may be drowned, and now a scientist tells us that there seems to be a peculiar fatality among fishes. After reaching a certain depth of water, the swimming bladders become distended by the pressure of air, and the fish literally explode. Too much of one's native element may bring about most disastrous consequences. A sudden change of air from one density to another may cause the rupture of a blood-vessel, and a too sudden change of temperature has produced like results. Extremes of all sorts are not only very injurious, but are likely to prove fatal, especially to organisms that are not in the enjoyment of robust health.

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended April 9, 1898:

Small-Pox—United States.

		Cases.	Deaths.
Alabama, Hurricane Bayou	March 27th to April 1st	5	
Mobile	March 27th to April 1st	3	
District of Columbia, Washington	April 2d	1	
Louisiana, New Orleans	March 26th to April 2d	2	
Michigan, Ionia	April 2, small-pox reported.		
Tennessee, Bristol	March 1st to 31st	1	
Chattanooga	March 1st to 31st	12	
Elk Valley	March 1st to 31st	1	
Jellico	March 1st to 31st	1	
Johnson City	March 1st to 31st	2	
Knoxville	March 1st to 31st	17	
Mingo	March 1st to 31st	1	
Morristown	March 1st to 31st	5	
Rockford	March 1st to 31st	1	
Rutledge	March 1st to 31st	11	
Shield's Ferry	March 1st to 31st	4	
Sprowles	March 1st to 31st	1	

Small-Pox—Foreign.

Bohemia, Prague	March 12th to 19th	6	
China, Hong Kong	February 12th to 19th	38	18
Cuba, Cienfuegos	March 20th to 27th	..	2
Sagua la Grande	March 12th to 26th	146	12
England, London	March 5th to 12th	1	
Sunderland	March 12th to 19th	1	
India, Calcutta	February 12th to 19th	..	2
Madras	February 19th to March 4th	..	22
Norway, Christiana	March 12th to 19th	14	
Russia, Odessa	March 5th to 19th	9	2
St. Petersburg	March 5th to 19th	13	3
Warsaw	March 5th to 12th	..	7

Cholera—Foreign.

India, Calcutta	February 12th to 19th	..	21
Madras	February 19th to March 4th	..	21

THE CHOICE OF ROUTES, ABDOMINAL OR VAGINAL, IN INTRAPELVIC SURGERY.

By CLEMENT CLEVELAND, M.D.,

NEW YORK.
